ANSWERS ABOUT ALDOMET® (METHYLDOPA|MSD)

Will an antihypertensive generally allow a normal cardiovascular response to exercise?

Cardiac output and blood pressure normally increase with increasing physical activity. ALDOMET does not significantly impair normal fluctuations of blood pressure during exercise.[1,2]

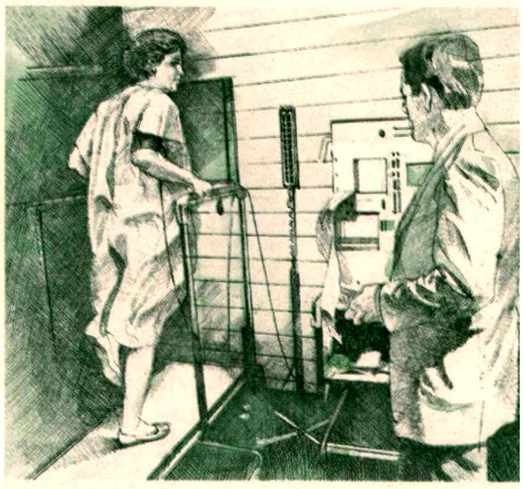
In a recent study of hypertensive patients whose cardiovascular response to exercise was evaluated before and during methyldopa therapy, "...methyldopa significantly reduced the rise in systolic pressure during the build-up ($P<0.01$) and subjective maximal stages ($P<0.05$) as well as at all phases of recovery ($P<0.01$)." Moreover, "The total duration of exercise (an index of work capacity) was unchanged with...methyldopa."[3]

Such findings can be of importance to active hypertensive patients such as the athletic individual or the person whose work requires substantial physical effort. For these and many other hypertensive patients, ALDOMET represents a logical therapeutic choice.

- With ALDOMET, exercise hypotension rarely occurs.
- Sedation, usually transient, may occur during the initial period of therapy or whenever the dose is increased.
- Headache, asthenia, or weakness may be noted as early and transient symptoms.

ALDOMET® offers many (METHYLDOPA|MSD) other important features:

- Highly effective in all degrees of hypertension.
- Existing cardiac output is usually maintained.
- Renal blood flow is usually maintained.
- Has documented long-term efficacy.
- Significant adverse effects have been infrequent and the agent is usually well tolerated.



ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, and if prev methyldopa therapy has been associated with li disorders. It is important to recognize that a posi Coombs test, hemolytic anemia, and liver disor may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disord could lead to potentially fatal complications unl properly recognized and managed.

For hypertension—

ALDOMET®
(METHYLDOPA | MSD)

The most prescribed nondiuretic antihypertensive in the U.S. today

ıtraindications: Active hepatic disease, such as te hepatitis and active cirrhosis; if previous thyldopa therapy has been associated with liver ɔrders (see Warnings); hypersensitivity.

rnings: It is important to recognize that a ıitive Coombs test, hemolytic anemia, and liver ɔrders may occur with methyldopa therapy. The e occurrences of hemolytic anemia or liver ɔrders could lead to potentially fatal complica- ns unless properly recognized and managed. ad this section carefully to understand these ıctions.

h prolonged methyldopa therapy, 10% to 20% of tients develop a positive direct Coombs test, ually between 6 and 12 months of therapy. Lowest ɔlence is at daily dosage of 1 g or less. This on casions may be associated with hemolytic h could lead to potentially fatal compli- predict which patients with a Coombs test may develop hemolytic . Prior existence or development of a positive ect Coombs test is not in itself a contraindication to of methyldopa. If a positive Coombs test velops during methyldopa therapy, determine ether hemolytic anemia exists and whether the itive Coombs test may be a problem. For ımple, in addition to a positive direct Coombs test e is less often a positive indirect Coombs test ich may interfere with cross matching of blood.

he start of methyldopa therapy, it is desirable to do lood count (hematocrit, hemoglobin, or red cell unt) for a baseline or to establish whether there is nia. Periodic blood counts should be done g therapy to detect hemolytic anemia. It may be ıl to do a direct Coombs test before therapy and 6 and 12 months after the start of therapy. If ombs-positive hemolytic anemia occurs, the use may be methyldopa and the drug should be ɔntinued. Usually the anemia remits promptly. If t, corticosteroids may be given and other causes anemia should be considered. If the hemolytic emia is related to methyldopa, the drug should not reinstituted. When methyldopa causes Coombs sitivity alone or with hemolytic anemia, the red cell usually coated with gamma globulin of the IgG ammaG) class only. The positive Coombs test may t revert to normal until weeks to months after ethyldopa is stopped.

ıould the need for transfusion arise in a patient ɔeiving methyldopa, both a direct and an indirect ombs test should be performed on his blood. In absence of hemolytic anemia, usually only the ect Coombs test will be positive. A positive direct ombs test alone will not interfere with typing or ɔss matching. If the indirect Coombs test is also sitive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses of anesthetics; hypotension occurring during anesthesia usually can be controlled with vasopressors. Hypertension has recurred after dialysis in patients on methyldopa because the drug is removed by this procedure.

Adverse Reactions: *Central nervous system:* Sedation, headache, asthenia or weakness, usually early and transient; dizziness, lightheadedness, symptoms of cerebrovascular insufficiency, paresthesias, parkinsonism, Bell's palsy, decreased mental acuity, involuntary choreoathetotic movements; psychic disturbances, including nightmares and reversible mild psychoses or depression.

Cardiovascular: Bradycardia, aggravation of angina pectoris. Orthostatic hypotension (decrease daily dosage). Edema (and weight gain) usually relieved by use of a diuretic. (Discontinue methyldopa if edema progresses or signs of heart failure appear.)

Gastrointestinal: Nausea, vomiting, distention, constipation, flatus, diarrhea, mild dryness of mouth, sore or "black" tongue, pancreatitis, sialadenitis.

Hepatic: Abnormal liver function tests, jaundice, liver disorders.

Hematologic: Positive Coombs test, hemolytic anemia. Leukopenia, granulocytopenia, thrombocytopenia. Positive tests for antinuclear antibody, LE cells, and rheumatoid factor.

Allergic: Drug-related fever, lupus-like syndrome, myocarditis.

Other: Nasal stuffiness, rise in BUN, breast enlargement, gynecomastia, lactation, impotence, decreased libido, dermatologic reactions including eczema and lichenoid eruptions, mild arthralgia, myalgia.

Note: Initial adult dosage should be limited to 500 mg daily when given with antihypertensives other than thiazides. Tolerance may occur, usually between second and third months of therapy; increased dosage or adding a diuretic frequently restores effective control. Patients with impaired renal function may respond to smaller doses. Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease; this may be avoided by lower doses.

How Supplied: Tablets, containing 125 mg methyldopa each, in bottles of 100; Tablets, containing 250 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 1000; Tablets, containing 500 mg methyldopa each, in single-unit packages of 100 and bottles of 100 and 500.

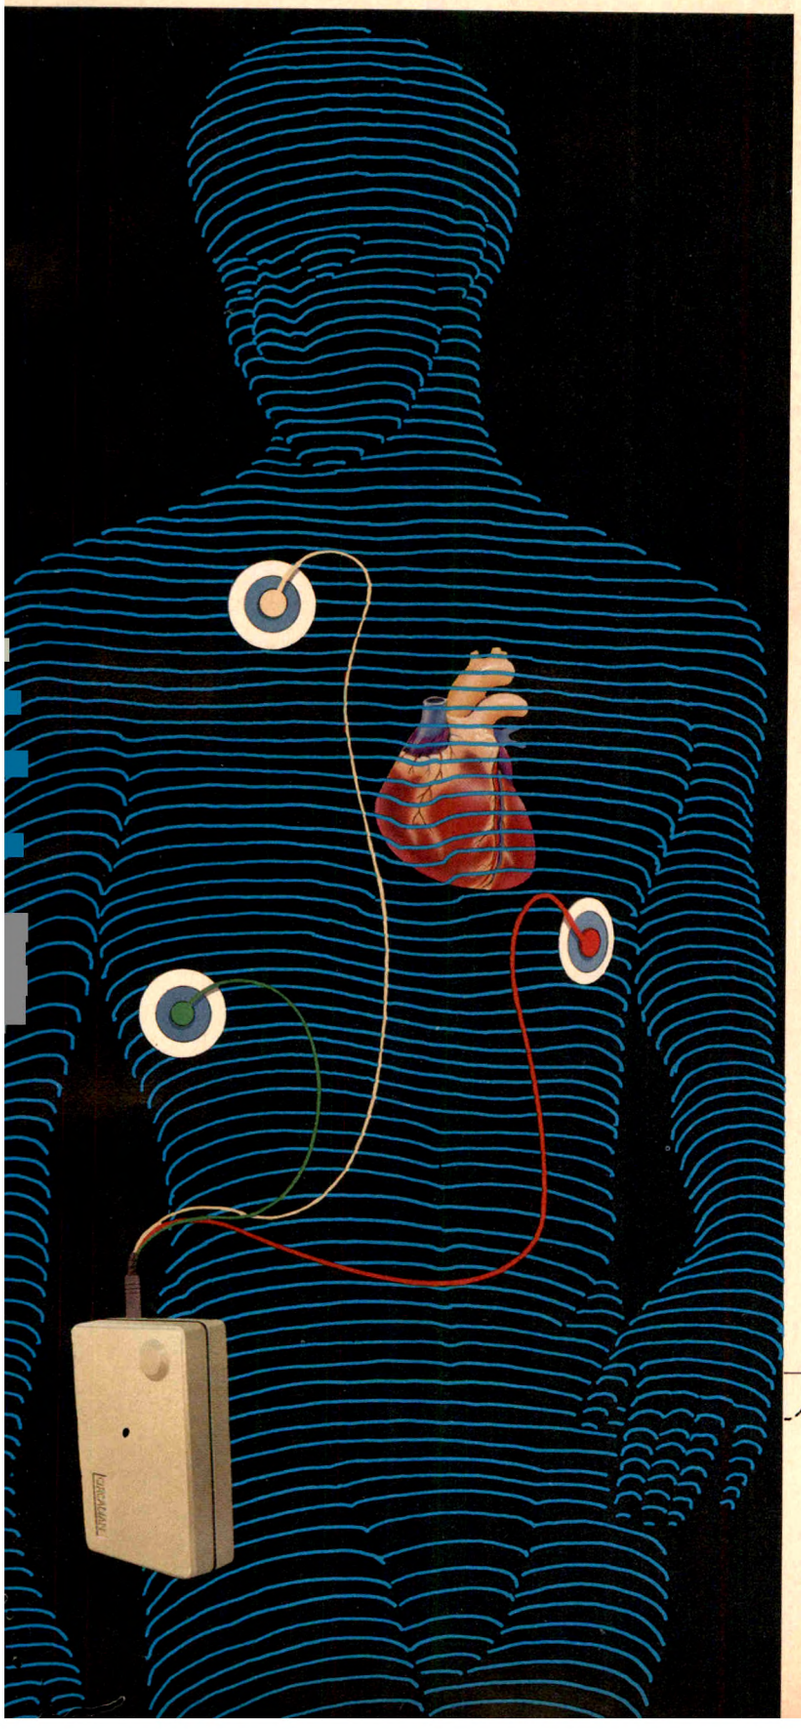
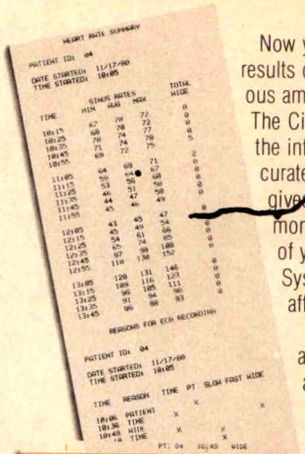
P 24,128

[illegible] Simple. Affordable. State of the art.





Now you can have all the relev results of up to three days contin ous ambulatory ECG monitoring. The CircaMed System summari the information into a short curate, complete printout gives you the benefit of monitoring with only minute of your time. The Circa System is affordable.

The CircaMed an ambulatory EC and cardiac rate mo Microcomputer co it ca stores 144 he rate summari per day.

When the monitor detec an abnormally high or low rate, or an unusually wide beat, a ten second tape recording of the ECG is activated. The patien may also activate a recording; the system will record at least one ten second ECG every thirty minutes. The time and reaso for each recording are stored in memory.

The Central Control Module translates Monitor informa- tion into a print-out of each heart rate summary, plus a print- out of time and reason for each ECG recorded.

The Chart Recorder Module provides a chart print-out the taped ECG measurements, annotated with patient numbe recording time, and reason for recording.

The CircaMed System is designed and priced for your office, yet it delivers the sophisticated capabilities of a large hospital system.

Fill in the coupon and we'll be glad to show you just how easy state of the art ECG monitoring can be.

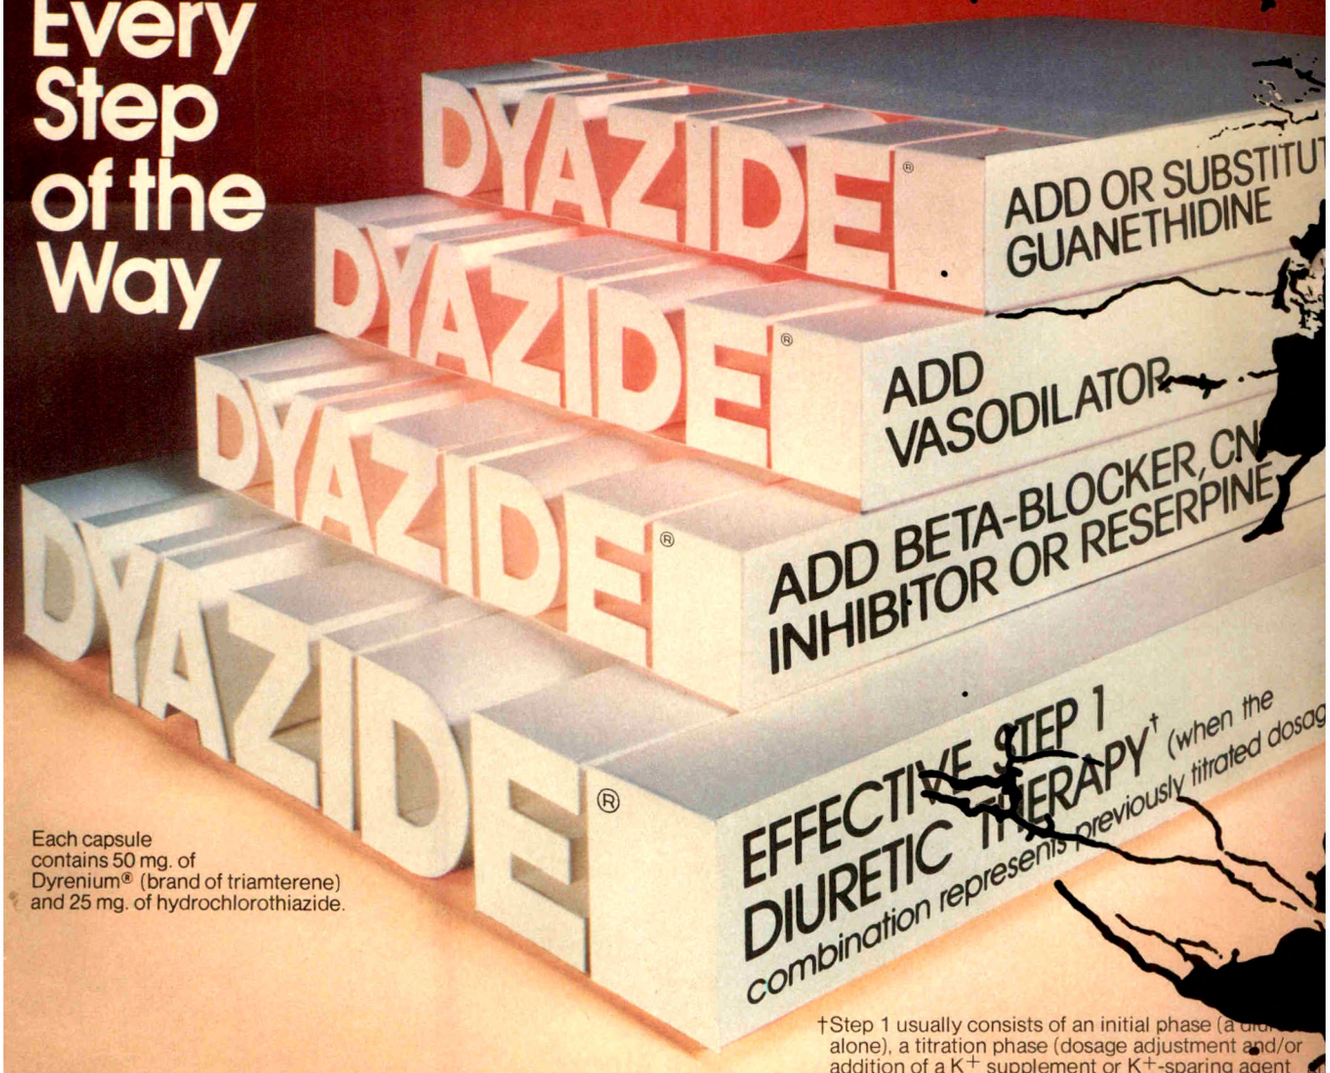
In Hypertension...When You Need to Conserve K

Every Step of the Way



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

†Step 1 usually consists of an initial phase (a diu alone), a titration phase (dosage adjustment and/or addition of a K^+ supplement or K^+-sparing agent a maintenance phase (a diuretic alone or in combinatio with a K^+ supplement or K^+-sparing agent).

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F Co. literature or *PDR*. A brief summary follows:

* **WARNING**
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K^+ frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in postsympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes wi fluorescent measurement of quinidine. Hyp kalemia, although uncommon, has been repo Corrective measures should be instituted cautiousl and serum potassium levels determined. Disc tinue corrective measures and 'Dyazide' sh laboratory values reveal elevated serum potass Chloride deficit may occur as well as dilut hyponatremia. Serum PBI levels may decrease w out signs of thyroid disturbance. Calcium excretio is decreased by thiazides. 'Dyazide' should be with drawn before conducting tests for parathyroid function.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

new 50 mg tablets...

Persantine®-50
(dipyridamole)

21% savings (over 25 mg)

NEW dosage convenience— one tablet instead of two

NEW prescribing flexibility— Persantine now available in three strengths...25 mg, 50 mg and 75 mg

Persantine® (dipyridamole)

INDICATIONS—Based on a review of this drug by the National Academy of Sciences National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine tablets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day taken at least one hour before meals. In some cases, higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25 mg, 50 mg and 75 mg

For complete details, please see the full prescribing information.

offer SPARKLING FAST DISSOLUTION

- ad[y] in *seconds* instead of minutes
- dissolution so unique it's patented*
- pleasant citrus flavor
- each packet delivers 20 mEq of potassium and chloride
- easily carried in patient's pocket or purse
- can be mixed with water or other liquid for pleasant daily dosage
- sugar, sodium, carbohydrate and dye free

ive your patients the KLORVESS sparkle

Please see brief summary of prescribing information on adjoining page.

Pat. No. 4,0[illegible],710

Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

New evidence is in:

Treatment of mild hypertension can save lives

Even among patients with DBP in the low 90s, systematic therapy significantly reduced mortality:

- Of nearly 11,000 hypertensives identified by the Hypertension Detection and Follow-up Program, slightly more than 70% had mild hypertension (DBP 90-104 mm. Hg).[1]
- Half were given systematic and aggressive care in HDFP centers; half were referred to customary sources of medical care.
- After 5 years, HDFP found that effective treatment of mild hypertension may reduce premature deaths by 20%.[1]
- As part of HDFP's systematic treatment and follow-up program, the primary step-1 agent was chlorthalidone: Hygroton®.[2]

The primary agent used by the HDFP in an effective low dose

Hygroton® 25 mg. one a day
(chlorthalidone USP)

Because there's nothing mild about mild hypertension

EF SUMMARY
cations: Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to rthalidone or other sulfonamide-derived drugs. **Warnings:** Should be used with caution in severe renal ase, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other hypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. re is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are ed to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and ear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against sible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly r adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier appear in breast milk. If use of the drug is essential, the patient should stop nursing. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be ormed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine trolyte determinations are particularly important when the patient is vomiting excessively or receiving nteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is ent, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake lso contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific ment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain nts. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes tus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn.
Usual Dose: One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored), 50 mg. (aqua) in bottles of 100, 1000 and 5000; 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips).

CLINICAL STUDIES

1 **Gated Cardiac Blood Pool Imaging and Thallium-201 Myocardial Scintigraphy for Detection of Remote Myocardial Infarction**

ALAN J. TIEFENBRUNN, DANIEL R. BIELLO, EDWARD M. GELTMAN, BURTON E. SOBEL, BARRY A. SIEGEL and ROBERT ROBERTS

This prospective study of 32 patients in whom infarct size was estimated enzymatically at the time of the acute episode and in 10 patients without infarction revealed thallium-201 imaging and radionuclide ventriculography are sensitive, noninvasive techniques for identifying prior myocardial infarction. They are particularly helpful in patients with conduction abnormalities or equivocal electrocardiographic findings. The sites of perfusion defects and of wall motion abnormalities corresponded closely and were concordant with electrocardiographic localization. Scintigraphically detectable perfusion defects persist for at least 6 months and, presumably, indefinitely. Radionuclide ventriculography also provides additional information characterizing late left ventricular function.

7 **Left Ventricular Function in Mitral Valve Prolapse: Assessment With Radionuclide Cineangiography**

JOHN S. GOTTDIENER, JEFFREY S. BORER, STEPHEN L. BACHARACH, MICHAEL V. GREEN and STEPHEN E. EPSTEIN

Radionuclide cineangiography in 47 patients with mitral valve prolapse at rest and during exercise identified a small subgroup without mitral regurgitation in whom diminished left ventricular functional reserve, manifested by an abnormal ejection fraction response to exercise, suggested a cardiomyopathic process. No patient in this series showed regional left ventricular dysfunction. The absence of these abnormalities on radionuclide cineangiography excludes with high probability the presence of coexisting significant coronary artery disease. Chest pain, arrhythmia and the pattern or degree of mitral valve prolapse on echocardiography were not independently associated with impaired left ventricular functional reserve.

14 **Cardiac Function During Rest and Exercise in Patients With Mitral Valve Prolapse. Role of Radionuclear Angiography**

GLENN E. NEWMAN, RAYMOND J. GIBBONS and ROBERT H. JONES

Assessment of ventricular function during rest and exercise in 12 patients with angiographically documented mitral valve prolapse and normal coronary anatomy, in 11 patients with normal coronary anatomy and no mitral valve prolapse, and in 11 additional patients with echocardiographically demonstrated mitral valve prolapse showed increased ejection fraction and no wall motion abnormalities during exercise. A decreased ejection fraction and wall motion abnormalities during exercise were found in 6 of 11 patients with mitral valve prolapse and angiographically demonstrated coronary arterial stenosis. These results suggest exercise-induced abnormalities in ventricular function are related to the presence and severity of coronary artery disease and not to mitral valve prolapse. Consequently, changes in ventricular function from rest to exercise assessed with radionuclide cineangiography can distinguish patients with mitral valve prolapse alone from those with prolapse and coronary artery disease.

When it's time for replacement... Spectrax-VL™ pacemaker.

To make it a long time between replacements, nature often starts small. She conserves energy. And so does Medtronic, in the Spectrax-VL. Medtronic provides exceptional longevity and reliable performance in a fixed rate pacemaker that's only 48 grams.

Spectrax-VL is the new generation of pacemakers from the long-lived Spectrax family, for your chronic patient who does well without programmability. The universal connector means Spectrax-VL accepts most manufacturers' leads *without adaptation*. And the fixed-rate Spectrax-VL allows you to make an automatic threshold safety margin check by telephone.

Spectrax-VL features Medtronic's proven constant energy and constant rate. As an indication of replacement, rate drops 10%.

Medtronic's technological leadership in pacing, leads and support mean you can offer many adults and children a more comfortable, normally active life with Spectrax-VL. And that's a tall order.

Spectrax. Broadening the spectrum of precise patient management.

Medtronic

Leading the way to man's heart.

MEDTRONIC PRODUCT INFORMATION SUMMARY

Medtronic® Implantable Pulse Generators

Intended Uses—Ventricular pacing using an implantable ventricular pulse generator and lead system are for long-term therapeutic control of heart rate in patients with impulse formation or conduction disorders leading to bradyarrhythmias, tachyarrhythmias and heart block (see product labeling for detailed list of intended uses). An atrial pulse generator is for long-term therapeutic control of heart rate in patients with impulse formation disorders but with intact, functioning A-V conduction systems.

Contraindications—There are no known contraindications to the use of pacing as a therapeutic modality for the control of heart rate in patients with normal conduction systems. In certain patients with anomalies of the conduction system (WPW syndrome and related conditions), patients may be benefited or harmed by cardiac pacing. Therefore, electrophysiologic studies are required prior to therapeutic application of pacing. In addition, the patient's age and medical condition may dictate the particular pacing system and implantation procedure used by the physician.

Warnings—Diathermy should not be used on patients with pacemakers because of possible heat damage to electronic components. Electrosurgical units should never be used in the vicinity of unipolar pulse generators or bipolar pulse generators implanted in the unipolar mode because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. (See product labeling for a complete list of warnings and precautions.)

Precautions—The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also, that the pacing system may cease to function at any time due to lead-related problems such as displacement, fibrotic tissue formation, elevated thresholds and perforations, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects—Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

Model 9700/9701 Programmers

Intended Use—The Medtronic® Model 9700 and 9701 Programmers are designed to be used by a physician for noninvasively programming the Medtronic® pulse generators listed in their respective technical manuals. The programmers may also be used to measure the rate and pulse width of implanted pacemakers.

There are no known contraindications or major potential complications associated with use of the programmer. However, these devices should not be used without prior study of the technical manual supplied with each programmer.

Warnings—The programmers should only be used for programming the Medtronic® pulse generators designated in the respective technical manuals. Direct stimulation by energy coupling may occur if the programmers are used on other implanted devices. The programmers are not compatible with pulse generators of other manufacturers. See product labeling for a complete list of warnings and precautions.

(spironolactone)

WARNING

Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats (see Warnings). Aldactone should be used only in those conditions described under Indications. Unnecessary use of this drug should be avoided.

Indications: *Diagnosis and treatment of primary hyperaldosteronism. Essential hypertension, edema of congestive heart failure and the nephrotic syndrome, when other measures are considered inappropriate. Cirrhosis of the liver accompanied by edema and/or ascites. Hypokalemia.*

Contraindications: *Anuria, acute renal insufficiency, significant impairment of renal function, or hyperkalemia.*

Warnings: *Excessive potassium intake may cause hyperkalemia. Potassium supplements should not be given with Aldactone. Do not administer concurrently with other potassium-sparing diuretics.*

Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. In one study using 25, 75, and 250 times the usual daily human dose (2 mg./kg.) there was a statistically significant dose-related increase in benign adenomas of the thyroid and testes. In female rats there was a statistically significant increase in malignant mammary tumors at the mid-dose only. In male rats there was a dose-related increase in proliferative changes in the liver. At the highest dosage level (500 mg./kg.) the range of effects included hepatocytomegaly, hyperplastic nodules and hepatocellular carcinoma; the last was not statistically significant.

Precautions: *Patients should be carefully evaluated for possible disturbances of fluid and electrolyte balance. Hyperkalemia may occur in patients with impaired renal function or excessive potassium intake and can cause cardiac irregularities which may be fatal. Hyponatremia may be caused or aggravated, especially when Aldactone is administered in combination with other diuretics. Transient elevation of BUN and/or mild acidosis may occur. Aldactone potentiates the effect of other diuretics or antihypertensive agents, particularly ganglionic blocking agents; therefore the dosage of such drugs should be reduced by at least 50 percent when adding Aldactone. Gynecomastia may develop and in rare instances some breast enlargement may persist. Vascular responsiveness to norepinephrine may be reduced.*

Spironolactone may cross the placental barrier. Use in pregnant women requires that the anticipated benefit be weighed against possible hazard to the fetus. Breast feeding should be discontinued when Aldactone is being used.

Adverse Reactions: *Gynecomastia is observed not infrequently. Gastrointestinal symptoms including cramping and diarrhea, drowsiness, lethargy, headache, maculopapular or erythematous cutaneous eruptions, urticaria, mental confusion, drug fever, ataxia, inability to achieve or maintain erection, irregular menses or amenorrhea, postmenopausal bleeding, hirsutism and deepening of the voice. Carcinoma of the breast has been reported but a cause-and-effect relationship has not been established. Adverse reactions are usually reversible upon discontinuation of the drug.*

Dosage and Administration

For primary hyperaldosteronism: *400 mg. daily for three to four weeks (long test), or for four days (short test). For preparation for surgery or for long-term maintenance therapy, 100 to 400 mg. daily.*

For edema in adults: *Initial daily dosage is 100 mg. in divided doses but may range from 25 to 200 mg. daily. If after five days an adequate diuretic response has not occurred, a second diuretic which acts more proximally in the renal tubule may be added. The dosage of Aldactone should remain unchanged when other diuretic therapy is added.*

For edema in children: *Initial daily dosage should provide approximately 1.5 mg. per pound of body weight (3.3 mg./kg.) in divided doses.*

For essential hypertension: *Initial adult daily dosage of 50 to 100 mg. in divided doses, alone or with diuretics which act more proximally in the renal tubule, or with other antihypertensive agents. Continue treatment for at least two weeks since maximal response may not occur before this time. Adjust subsequent dosage according to patient response.*

For hypokalemia: *25 to 100 mg. daily in divided doses.*

SEARLE *Searle & Co.*
San Juan, Puerto Rico 00936

Address medical inquiries to:
G. D. Searle & Co.
Medical Communications Department
Box 5110, Chicago, Illinois 60680

inadequate or inappropriate

Aldactone®
(spironolactone 25 mg)

The uncomplicator in CHF therapy

"Round-the-house" edem
electrolyte washout, subt
secondary volume buildu

☑ *Aldactone, an effective diuretic in its own right, also enhances the efficacy of other diuretic agents.*

☑ *The unique potassium-regulating mechanism of Aldactone can prevent hypokalemia with limited risk of hyperkalemia. This helps protect your patient from digitalis-induced arrhythmias.*

☑ *Unlike other potassium-sparers, Aldactone specifically antagonizes aldosterone, thereby mitigating secondary volume buildup.*

For these reasons, Aldactone is a valuable adjunct in the treatment of CHF.

Limitations to Consider: *Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. Thus, Aldactone should be prescribed only when other measures are considered inadequate or inappropriate. (See boxed warning and* Warnings *section of Aldactone prescribing information.)*

Before prescribing, please consult the complete prescribing information, a brief summary of which appears on the preceding page.

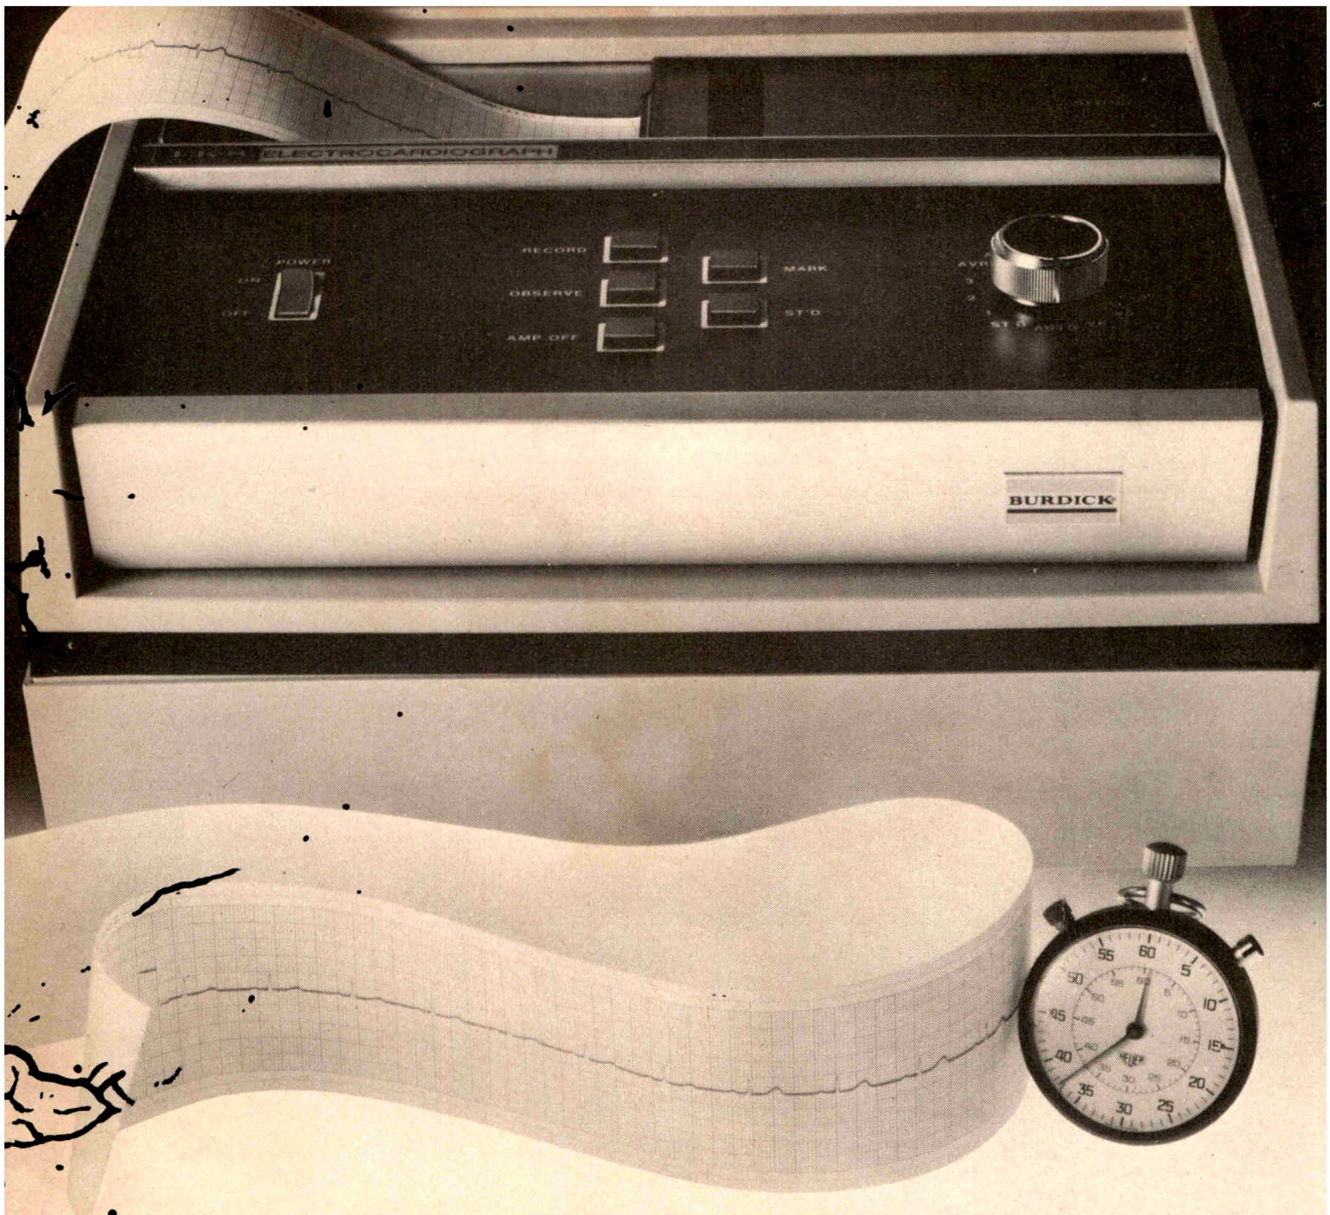
U10



Burdick produces the 38-second electrocardiogram

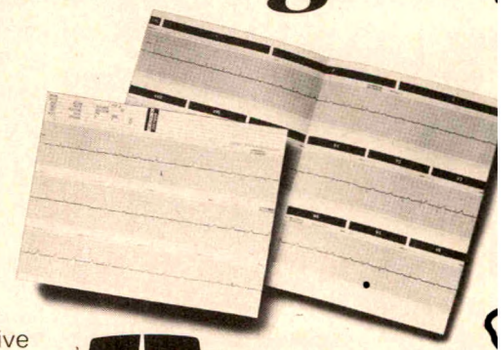
In fact, only 37.4 seconds to record the complete 12-lead electrocardiogram. It's the EK-8, Burdick's first fully automatic single-channel electrocardiograph.

Combined with its unique mounting system, the EK-8 assures higher ECG productivity, substantial savings of time for operator and staff and important savings on ECG paper.

Each lead is recorded in proper sequence—with lead lengths and lead switching on every lead automatically controlled. With proper technic there is no stopping to move the chest lead, fewer overruns, less waste, more ECG's per roll. That means additional savings.

Important savings of technician and staff time are possible with the EK-8's unique mounting system. Leads are automatically identified, and the complete 12-lead tracing is ready for mounting on Burdick self-adhesive card or folder formats, ready for filing. In the folder-mode, with longer leads for additional data, the complete ECG is recorded in 47.1 seconds. Manual override provides full choice of lead lengths if desired.

The faster Burdick EK-8. Because time is your valuable asset for better patient service. For more information, or a demonstration, call us toll-free at 800-356-0701: In Wisconsin call 608-868-7631. Or write **The Burdick Corporation, Milton, Wisconsin 53563.**



Burdick®

A concern for cardiac care.

20 Exercise Cross-Sectional Echocardiographic Diagnosis of Coronary Artery Disease

JOEL MORGANROTH, CHIN C. CHEN, DANIEL DAVID, HENRY S. SAWIN, MASAHITO NAITO, CONNIE PARROTTO and LINDA MEIXELL

Wide angle cross-sectional echocardiography in 55 patients undergoing diagnostic coronary arteriography show that new regional wall motion abnormalities during exercise represent a specific finding for the presence of coronary artery disease. Such studies were adequate for analysis in 43 (78 percent) of the 55 subjects. Normal regional wall motion during exercise did not exclude the presence of important anatomic coronary artery disease. About 50 percent of the patients with normal regional wall motion during exercise had important anatomic coronary artery disease and half of these had abnormal S-T segment depression during exercise testing. For this group, the electrocardiographic manifestation of ischemia proved more sensitive in predicting the presence of anatomic coronary artery disease than did the presence of new regional wall motion abnormalities on two dimensional echocardiography during exercise.

27 Importance of Coronary Collateral Circulation in Interpreting Exercise Test Results

JULIO F. TUBAU, BERNARD R. CHAITMAN, MARTIAL G. BOURASSA, JACQUES LESPÉRANCE and GEORGES DUPRAS

Examining the hypothesis that coronary collateral circulation can cause false negative exercise electrocardiograms and myocardial scintigrams, this study of 37 patients with 90 percent or greater isolated stenosis of the luminal diameter in one major coronary artery and no other arterial stenosis of 50 percent or greater concludes that large intercoronary collateral vessels are a common cause of false negative scintigrams rather than of false negative exercise electrocardiograms, which are largely unaffected by the degree of collateralization. Large collateral vessels may limit the quantity and location of myocardial ischemia. Exercise electrocardiography and thallium-201 scintigraphy may detect different aspects of ischemia.

33 Lack of Correlation Between Exercise Capacity and Index of Resting Left Ventricular Performance in Heart Failure

JOSEPH A. FRANCIOSA, MARY PARK and T. BARRY LEVINE

Treadmill exercise performed in 21 patients with heart failure caused by cardiomyopathy indicated that measures of left ventricular performance obtained at rest do not accurately reflect exercise tolerance and symptomatic status of patients with congestive heart failure. Exercise duration averaged 9.1 ± 7 minutes (normal value 12 or more minutes) and did not correlate with resting ejection fraction of 26.4 ± 2.7 percent. Left ventricular diastolic dimensions of 6.6 ± 0.2 cm determined with M mode echocardiography, mean velocity of circumferential fiber shortening and ratio of preejection period to left ventricular ejection time did not correlate with treadmill time. It is quite likely that hemodynamic responses and change in ventricular performance during exercise are major determinants of exercise capacity in patients with heart failure.

40 Systolic and Diastolic Properties of the Human Left Ventricle During Valve Replacement for Chronic Mitral Regurgitation

CALVIN Y. H. WONG and HENRY M. SPOTNITZ

Using M mode and two dimensional echocardiography and intraoperative measures of hemodynamic function, ventricular compliance and systolic mechanics in nine patients during valve replacement for chronic mitral regurgitation, these investigators detected large decreases in early postoperative shortening fraction. Elimination of the low impedance left atrial pathway by valve replacement was associated with a significant increase in wall stress that appears responsible for the decreased ejection fraction postoperatively. Other data emphasize the unreliability of preoperative ejection fraction as an index of cardiac reserve in patients with chronic mitral regurgitation and suggest the need for improved methods of evaluating patients with this condition as candidates for surgery. Conventional analysis of ejection fraction preoperatively underestimates the degree of left ventricular dysfunction.

At Clinical Data, we asked ourselves... What should we do with the world's most accurate and readable long-term ECG report?"

Introducing an even more accurate and readable LCG™ Report.

That's the trouble with being number one . . . you're never satisfied. And that's why, if you subscribe to Clinical Data's long-term ECG (Holter) recording service, *you* always will be satisfied.

Because *we* do all the worrying. All the research. All the up-dating to the latest technology. And all the "back to the drawing boards" redesigning of the reporting format that has become the state of the art—in a super competitive field.

Our latest format features several new presentations of ectopic data.

It not only gives you more data, but it also makes that data easier to find and understand. The result? Easier interpretation and a more confident diagnosis.

It's the end result of doing everything right.

The right recording technique, with a one pound, 24-hour, continuous two-lead FM cassette recorder with a crystal controlled timing track.

The right reviewing technique, with Clinical Data's exclusive Stein/Peterson™ Examination Technique which introduced stationary ECG presentations to Holter recording.

And the right reporting technique, with *no* data compression. With ECG strips, hourly heart rate, graphic and numerical quantitation of up to eight different ectopic foci validated by the examiner.

You get the picture? Even if you've seen one of Clinical Data's LCG reports, you really haven't seen one of Clinical Data's *new* LCG reports. We've made the best even better. Call or write. We'll send you one.

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

ODERN DRUG ENCYCLOPEDIA
nd Therapeutic Index 15th Edition
rthur J. Lewis, MD, Editor
ertrude Dittus Gonzales, R.Ph., Executive Editor
harles L. Winek, Ph.D., Contributing Editor

The all new 15th Edition of MODERN DRUG ENCYCLOPEDIA is ritten especially for the practitioner who needs complete, objec- ve information on prescription drugs.

An independent team of pharmacists and physicians has research- d and edited all the facts on 3,000 prescription drugs. They pass is research on to you in an easy to absorb style that's perfectly uited to the tight schedule of a time pressed practitioner.

ere's what careful planning does for MODERN DRUG NCYCLOPEDIA:
limits entries to prescription drugs.
lists over 3,000 pharmaceuticals, biologicals, and allergens in one alphabetic sequence.
arranges entries by generic name. All brand names in one place.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main secton as follows:

- GENERAL INDEX of all brand generic names in a-z sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selectin of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

And, our Free Updating Service informs you of changes in specifications and introduces new drugs. You receive them free of charge until the publication of the next (16th) Edition.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

YORKE MEDICAL GROUP, 666 Fifth Ave., NY, NY 10103

Please send me a copy of the all-new 15th Edition of MODERN DRUG ENCYCLOPEDIA and enter my two year free subscription to the Periodic Updating Service. If this new edition is the best drug information reference for practitioners available, I will remit $38.95, plus shipping. Otherwise, I will return it within 30 days and owe nothing.

☐ Check here if enclosing $38.95 now as full payment. Publisher pays shipping. Same return guarantee
☐ Charge my credit card: ☐ Master Charge ☐ Visa.

Danger: PVC's don't sleep!

In a study of patients with coronary artery disease, 25 percent showed an increase in PVC's during sleep.[1]

Prior to the Annual Meeting of the American Association of Thoracic Surgery

CURRENT CONTROVERSIES AND TECHNIQUES IN CONGENITAL HEART SURGERY

May 8 - 9, 1981 In Baltimore, Maryland

Sponsored by:
University of Maryland School of Medicine
Divisions of Cardiovascular Surgery and Pediatric Cardiology
American Heart Association, Maryland Affiliate

BUS TRANSPORTATION WILL BE PROVIDED TO THE AMERICAN ASSOCIATION OF THORACIC SURGERY MEETING IN WASHINGTON D.C. ON MAY 10, 1981.

GUEST PARTICIPANTS:

Robert Anderson, London, England
Frederick Bowman, New York City, NY
Gerard Brom, Leiden, Netherlands
Alain Carpentier, Paris, France
Gordon Danielson, Mayo Clinic, MN
Francis Fontan, Bordeaux, France
James Malm, New York City, NY
Albert Pacifico, Birmingham, AL
Lucio Parezan, Bergamo, Italy
Jaroslav Stark, London, England
Paul Ebert, San Francisco, CA

U. of M. SCHOOL OF MEDICINE LIBRARY

To reduce the risk of potentially fatal arrhythmias in patients with compromised hearts

324 mg
Quinaglute® DURA-TABS®
(quinidine gluconate)

- Practical b.i.d. or t.i.d. dosage protects night and day
- Less frequent administration helps improve patient compliance and thus helps assure needed round-the-cloc protection.[2]

References: 1. Schroeder, J.S.: Emergency Medicine **12**:34 (Feb. 15) 1980. 2. Lown, B., in Lown, B., and Segal, J.: Modern Medicine **46**:60 (Sept. 30-Oct. 15) 1978.

PVC's don't sleep!

324 mg

Quinaglute®

DURA-TABS®

(quinidine gluconate)

CONTRAINDICATIONS:
Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Partial A-V or complete heart block, or intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening.

Renal disease resulting in significant azotemia, or those developing cardiotoxic effects such as conduction defects, ventricular premature beats, ventricular tachycardia or flutter while on the drug.

Marked cardiac enlargement, particularly with congestive failure, poor renal function, and especially renal tubular acidosis.

Idiosyncrasy or hypersensitivity to quinidine.

WARNINGS:
In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate.

PRECAUTIONS:
The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate should be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy.

Quinidine in large doses may reduce the contractile force of the heart, therefore, extreme caution should be exercised in using the drug in patients with severe heart disease, hypotension or digitalis intoxication. The potential disadvantages and benefits must be weighed.

It should be administered cautiously, if at all, to senile patients.

Hospitalization for close clinical observation, electrocardiographic monitoring, and possibly plasma quinidine levels is indicated when large doses are used or with patients who present an increased risk.

ADVERSE REACTIONS:
Symptoms of cinchonism, ringing in ears, headache, nausea, disturbed vision may appear in sensitive patients after a single dose of the drug.

Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism, hypotension.

Gastrointestinal: Nausea, vomiting, abdominal pain, diarrhea.

Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranulocytosis.

Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision fields, photophobia, diplopia, night blindness, scotomata), optic neuritis.

Dermatologic: Cutaneous flushing with intense pruritus.

Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest.

See package insert for full information.

Timely Selections from PSG...

NONINVASIVE CARDIOVASCULAR DIAGNOSIS Second Edition
Edited by Edward B. Diethrich

Based on the Second International Cardiovascular Congress, this volume contains the complete presentations of almost 300 experts from around the world. It represents the most recent and advanced knowledge in noninvasive cardiovascular diagnosis. Topics include ultrasonic Doppler techniques; oculoplethysmography; evaluation of cardiovascular risks in surgical patients; assessment of peripheral vascular diseases; evaluation of coronary artery disease; physiology and techniques in cardiovascular diagnosis; echocardiographic diagnosis; and many other subjects. **630 pp $59.50**

UNSTABLE ANGINA Recognition and Management
Edited by Allan G. Adelman and Bernard S. Goldman

Covers in detail the recognition, diagnosis, and current management of unstable angina, treatment of left main coronary artery stenosis, severe left ventricular dysfunction, coronary artery spasm, and pre-infarction type of unstable angina. Emphasis is on decision-making process involved in treating and of the role of surgical and medical therapy. **326 pp $29.50**

MYOCARDIAL REVASCULARIZATION BY ARTERIAL/VENTRICULAR IMPLANTS
By Arthur M. Vineberg

Provides a detailed description and evaluation of direct myocardial revascularization by arterial/ventricular implants. A detailed presentation of the pertinent anatomy, physiology, and pathophysiology is given. Includes sections on preoperative investigation, anesthesia, postoperative care, physical therapy, diet, exercise, and rehabilitation of the cardiac patient. **624 pp $49.50**

HEALTH MAINTENANCE THROUGH PHYSICAL CONDITIONING
Edited by Robert C. Cantu

Based on extensive research, this guide to sensible health maintenance stresses the prevention of injuries by physical conditioning programs. Its theme is the maximization of physical and emotional health through an appropriate life-style based on moderate exercise, proper nutrition, and decreased self-pollution. Myths about exercise are also examined. **180 pp $12.50**

A CASEBOOK OF ELECTROCARDIOGRAPHIC TRACINGS With CME Component
By Jorge I. Martinez, Stephen P. Glasser, and Pamela I. Clark

Some seventy ECG cases are presented to illustrate important aspects in the use of electrocardiographs in the diagnosis of vascular disease. Each case consists of: a) an unknown ECG tracing captioned with pertinent patient data; b) diagnosis and elucidation; c) a discussion of the case; d) a listing of selected references for further study; e) the title of each case, providing a clue to the abnormality. CME questions and credits included. **In preparation.**

ADVANCES IN HUMAN CLINICAL NUTRITION
Edited by Joseph J. Vitale

With contributions from experts, the book provides an update on the latest information concerning nutrition. Special sections devoted to the possible relationship of dietary habits to cardivascular disease, cancer, obesity, and diabetes. Also considered is the question of prescribing megavitamin therapy. **In preparation.**

51 Right Ventricular Performance in Mitral Stenosis

EDMUND WROBLEWSKI, FRANK JAMES, JAMES F. SPANN and ALFRED A. BOVE

Assessing right ventricular performance from computer-analyzed biplane right ventriculograms in seven normal subjects and in eight patients with mitral stenosis, these investigators found patients with mitral stenosis had elevated systolic right ventricular pressure (57 ± 6 mm Hg) but normal right ventricular end-diastolic pressure (81 ± 9 ml/m^2) and ejection fraction (0.58 ± 0.04). Left ventricular function as measured by the ejection fraction was reduced in the patients with mitral stenosis. The contractile performance of the right ventricle in patients with mitral stenosis remains normal with moderate pressure overload when there is no clinical evidence of right ventricular failure. The normal function of the right ventricle is probably maintained by hypertrophy when the pressure overload is not extreme. The cause of the reduced left ventricular function in mitral stenosis is unclear.

56 Right Ventricular Function in Adult Atrial Septal Defect. Preoperative and Postoperative Assessment and Clinical Implications

RICHARD R. LIBERTHSON, CHARLES A. BOUCHER, H. WILLIAM STRAUSS, ROBERT E. DINSMORE, KENNETH A. McKUSICK and GERALD M. POHOST

This study of right ventricular function in 20 adults with an atrial septal defect illustrates the close correlation between right ventricular function and clinical course preoperatively and postoperatively in these patients. Nuclear imaging proved beneficial in such assessments. Preoperatively, the right ventricle was dilated in all 20 patients; right ventricular wall motion was normal in 9 who were asymptomatic and had normal sinus rhythm. These and other data demonstrate severe preoperative right ventricular hypocontractibility and indicate that postoperative right ventricular size and function improve but do not necessarily become normal. These observations support early prophylactic closure of atrial septal defect and favor surgical repair even in adult patients with abnormal preoperative right ventricular wall motion.

EXPERIMENTAL STUDIES

61 Acute Effects of Ethanol on Myocardial Blood Flow in the Nonischemic and Ischemic Heart

HOWARD S. FRIEDMAN with the technical assistance of CHARLES NEAL, ANDREW DOWD, EILEEN TAYLOR and EDWARD SHAUGHNESSY

Coronary blood flow, measured with radionuclide-tagged microspheres in the anesthetized dog before and after intravenous administration of 1.7 g/kg body weight of ethanol, increased in the nonischemic myocardium. In the acutely ischemic heart ethanol produced an unfavorable redistribution of myocardial blood flow with flow in the nonischemic myocardium increasing in part at the expense of blood flow to the ischemic myocardium. The increment of blood flow appeared greatest in the subendocardial nonischemic zone whereas the decrease in flow was greatest in the subepicardial ischemic zone. This study suggests that ethanol ingestion should be limited in patients with coronary heart disease because of its "coronary steal" effect, which increases the flow in the nonischemic areas at the expense of the blood flow to the ischemic myocardium.

METHODS

68 Derivation of Systolic Time Intervals From Doppler Measurement of Temporal Arterial Blood Flow

JAMES A. ROTHENDLER, EDGAR C. SCHICK, Jr. and THOMAS J. RYAN

Attention is drawn to a new method for recording systolic time intervals during exercise that utilizes the blood velocity profile of the superificial temporal centers measured by Doppler ultrasound. Doppler-derived left ventricular ejection time and preejection period showed excellent correlation with the conventional carotid pulse method and little intra- or interobserver variability. This method reduced motion artifact, permitted satisfactory tracings in 8 of 10 subjects who exercised through stage III of the Bruce treadmill protocol, and has potential value for use of the additional information inherent in the velocity profile.

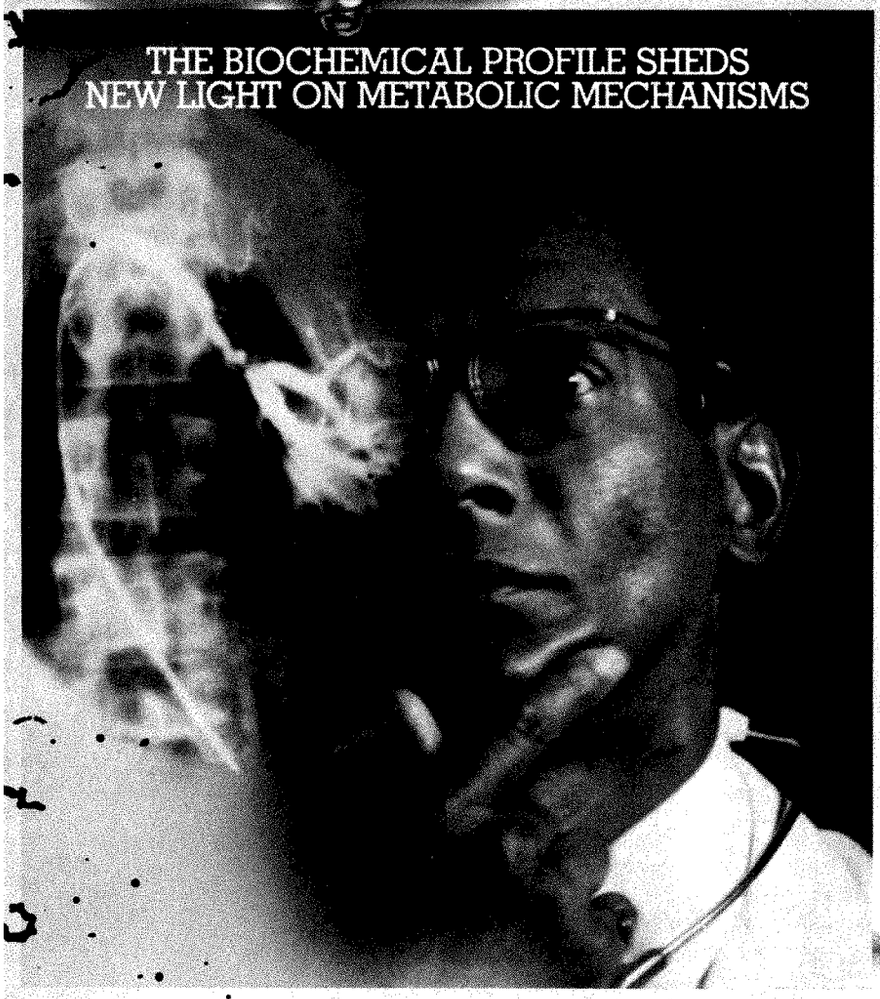
"PROFILING" TODAY'S HYPERTENSIVE PATIENT



THE BIOCHEMICAL PROFILE SHEDS NEW LIGHT ON METABOLIC MECHANISMS

While hypertension still remains an enigma, its metabolic pathways have become clearer in the past twenty years. One of the most important pathways involves the renin-angiotensin-aldosterone system. The kidney is known to secrete renin under three circumstances: 1) when the organ itself becomes ischemic; 2) when the body's sodium content is depressed; 3) when blood volume is reduced. Renin then catalyzes the conversion of the decapeptide angiotensin I to the octapeptide angiotensin II. Besides being the most potent vasopressor known,[1] angiotensin II also stimulates the adrenal gland to produce aldosterone. By enhancing renal reabsorption of sodium, aldosterone expands the body's sodium content and plasma volume. This reduces renin production and closes the loops of the negative feedback system. A breakdown in this system may result in higher levels of renin and angiotensin II—and sustained high blood pressure.

Disturbances in other mechanisms can also trigger metabolic chains of events that lead to hypertension. This increasing knowledge has generated interest in drugs designed to halt the hypertensive process at several points. One of the newest drugs is thought to inhibit the enzyme that converts angiotensin I into angiotensin II.[1] Equally important has been the development of more accurate diagnostic tests for "biochemical" profiling.

How useful is measuring renin activity? Some clinicians now advocate "renin profiling" of all hypertensives. This rather complicated test provides the renin-sodium index by indirectly measuring the renin level and comparing it to sodium intake. The index helps distinguish renin-dependent hypertensives (about 70% of patients) from those who are sodium-dependent. It is only the latter who are most likely to benefit from diuretics and the "stepped-care" approach.

While renin profiling can be very useful for selected patients, most physicians consider it unnecessary or impractical for routine evaluation. The initial choice of therapy rarely hinges on renin activity.[2] Also, the renin-sodium index is hard to obtain in non-hospitalized patients and may not offer any real advantages over a therapeutic trial that includes a diuretic (for low-renin patients) or a beta blocker (for high-renin patients).[2,3]

The lab workup that works for most patients Some authorities believe that a minimal workup is sufficient for roughly 90% of hypertensive patients.[3] This generally includes a hematologic profile, urinalysis, blood chemistry (covering a number of biochemical variables), along with the standard ECG and chest roentgenogram.[2,3] More exhaustive tests—including renal profiling, intravenous urograms and catecholamine level determinations—would only be ordered if secondary causes are suspected.

THE "PSYCHOLOGICAL PROFILE" ADDS VALUABLE INSIGHTS

At times, it reveals excessive anxiety A good deal of research has focused on the contributory role of psychological and social factors in the development of hypertension. Such factors have been found to increase plasma renin activity.[4] Consequently it is often recommended that some form of psychosocial profile be added to the patient's family and medical history.[2,5] Even though the hypertensive patient may seem calm, a few carefully worded questions often uncover intense psychic tension. The patient's anxiety may center on his psychological problems alone or may extend to the economic and social repercussions of his illness.

How psychological factors may affect the course of therapy Hypertensive patients with psychological problems may have difficulty in coping with the do's and don'ts of their therapeutic program... and with demoralizing new self-images as "chronically sick, potentially dependent" persons. The psychological profile helps the physician assess the patient's understanding of his illness, his emotional reactions to it, and the likelihood of his compliance with recommended therapy. This information can help set the stage for the mutually rewarding doctor-patient rapport essential to successful long-term management of any chronic illness.

Why Valium®(diazepam/Roche) can be valuable adjunctive therapy In many cases, your reassurance and continued support will be enough to relieve your patient's emotional distress. But for some patients, you may find that specific antianxiety medication is also warranted. It is at these times that Valium can be especially helpful. Valium works promptly and predictably to relieve the excessive psychic tension that often accompanies organic illness. Initial calming typically occurs within hours—more sustained and extensive symptomatic relief becomes manifest in a matter of days. With intense anxiety under control, the hypertensive patient is often better able to face his condition and to comply with your treatment program. Another important factor—Valium (diazepam/Roche) is used with most primary medications, including cardiac glycosides, diuretics and vasodilators.

Side effects more serious than drowsiness, fatigue and ataxia are rare and seldom severe. As with all CNS-acting agents, patients should be cautioned against drinking alcoholic beverages or driving. Periodic reassessment of the continued need for psychotropic medication is also recommended. Once the patient is again able to cope, Valium should be gradually discontinued. See guidelines on following page for further ways to optimize therapy with Valium.

VALIUM® (IV)

diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

WHEN ANXIETY DISORDERS HAMPER HIS ABILITY TO COPE

Before prescribing, please see brief summary of product information on following page.

ROCHE®

VALIUM® (IV)
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.
Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.
Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.
Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).
Supplied: Valium® (diazepam/Roche) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available in trays of 10.

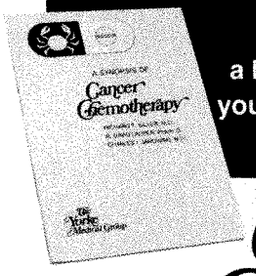
How to Keep Up with Drug Interaction in Cancer Chemotherapy



Three authorities from a leading medical center show you how to use the most current chemotherapeutic agents

A SYNOPSIS OF Cancer Chemotherapy

At last a way to keep up with the bewildering proliferation of new chemotherapeutic drugs which have come into use relatively recently. This recently published guide will be valuable to every hospital, and every oncology specialist, general internist, clinical pharmacist, and nurse oncologist.

A SYNOPSIS OF CANCER CHEMOTHERAPY is a concise, readily understandable "how to" manual. Developed originally for staff use at The New York Hospital-Cornell Medical Center, the concept proved so successful it was decided to make it available to other professionals. The new users of the SYNOPSIS have the advantage of a proven, time-tested learning system. It is written in a unique, compact work-book style to keep reading time to a minimum.

The reader can quickly find the following for both commercially available and investigational drugs:
- Structure
- Mechanism of Action
- Pharmacokinetics
- Toxicity
- Therapy
- Availability

The chemotherapeutic agents in the main listing section cover these categories:
- Alkylating Agents
- Antimetabolites
- Mitotic Inhibitors
- Antibiotics
- Miscellaneous (includes such drugs as Mithramycin, Mitotane, etc.)

RICHARD T. SILVER, MD, F.A.C.P., F.A.B.C.O.
Chief, Oncology Service, Div. Hematology-Oncology, Clinical Professor of Medicine, Cornell University Medical College, Attending Physician, New York Hospital, Exec. Officer, Cancer & Leukemia Group B.

R. DAVID LAUPER, Pharm. D.
Asst. Director for Education and Information, Pharmacy Dept., New York Hospital-Cornell Medical Center.

CHARLES I. JAROWSKI, MD
Instructor in Medicine, Cornell University Medical College, Senior Chemotherapy Fellow, Div. of Hematology-Oncology, The New York Hospital.

Use it for 30 days—FREE

Refer to it for chemotherapeutic drug information for a full month. Then keep the book only if you want it for permanent reference. Otherwise simply return it and owe nothing. You have nothing to lose and a whole world of valuable life-saving knowledge to gain. Order right now!

FAMOUS DOMES

One disposable dome stands out from every other in sight. Why? Probably because Bell & Howell's DISPOSADOME® excells in so many ways.

Some say they like the convenience . . . "It's so fast and easy!" (They refer to the individual snap-open sterile package and quick installation — you don't have to use a fluid between the membrane and the transducer diaphragm — and of course the disposable feature.)

Some quote the economy factor. (Yes, considering the time and labor costs for cleaning and sterilizing other types — plus the possibility of transducer damage — that's certainly true.)

Others agree to these advantages, but additionally cite the ready availability of either Linden or Luer fittings. (And, we might add, you can switch transducers or domes without disturbing the fluid path.)

Whatever your reasons for helping to make DISPOSADOME famous, you also have the assurance of the Bell & Howell name and experience. And that's really the best reason of all.

(DISPOSADOME is designed exclusively for use with Bell & Howell physiological pressure transducers.)

360 Sierra Madre Villa, Pasadena, California 91109 (213) 796-9381

EPIDEMIOLOGY

73 Predicting Cardiac Morbidity Based on Risk Factors and Coronary Angiographic Findings

JOEL E. DIMSDALE, JOHN GILBERT, ADOLPH M. HUTTER, THOMAS P. HACKETT and PETER C. BLOCK

Follow-up analysis of a cohort of 189 men for 1 year after coronary angiography reveals that 25 percent experienced a substantial cardiac morbid event—hospitalization, myocardial infarction, resuscitation or death. The most important risk factors for increased morbidity included severity of angina, history of myocardial infarction, family history of heart disease, fatigue and absence of type A behavior. For the medically treated group alone, the presence of electrocardiographic Q waves, age, stress and low level of acknowledgment of anger were discriminating variables. For the whole group the depression and low serum cholesterol were discriminating variables; the number of diseased vessels was not.

PEDIATRIC CARDIOLOGY

77 Lung Biopsy With Frozen Section as a Diagnostic Aid in Patients With Congenital Heart Defects

MARLENE RABINOVITCH, ALDO R. CASTANEDA and LYNNE REID

Assessment of pulmonary arterial development and structure by lung biopsy with frozen section proved helpful in deciding between a palliative and corrective surgical procedure in eight patients with congenital heart defects and equivocal preoperative hemodynamic data. Such morphologic assessment can be and was related to the degree of hemodynamic distribution of the circulation. As a result of the biopsy, six of the eight patients underwent corrective surgery and two a palliative procedure. Analysis of the pulmonary vascular changes was similar on the frozen and the paraffin-embedded sections. Postoperative hemodynamic data in four patients undergoing corrective surgery revealed either a significant reduction in pulmonary vascular resistance or return to a normal level of pulmonary arterial pressure and no change in the one patient who underwent a palliative procedure.

85 Ventricular Septal Defect in Infancy: Detection With Two Dimensional Echocardiography

JOHN P. CHEATHAM, LARRY A. LATSON and HOWARD P. GUTGESELL

In this study of 53 infants under 1 year of age two dimensional echocardiography detected approximately three fourths of ventricular septal defects large enough to warrant cardiac catheterization in the 1st year of life. Among the 27 patients with a ventricular septal defect, the lesion was correctly identified in 20 (74 percent) and was undetected in 7. No defect less than 4 mm in diameter was detected. False positive diagnoses were related to dropout of echoes in the membranous septum when imaging in the four chamber views. Factors affecting the sensitivity of two dimensional echocardiography in the detection of ventricular septal defects include the resolution of the ultrasonic equipment, the anatomic location of the defect, the composition of the study group and the skill and bias of the ultrasonographer. This technique appears most useful when other cardiac anomalies may mask a large ventricular septal defect.

90 Postnatal Endocardial Fibroelastosis of the Valve of the Foramen Ovale

GROVER M. HUTCHINS, G. WILLIAM MOORE, JOCELYN F. JONES and STEPHEN T. MILLER

Examination of 200 hearts from embryos, fetuses and necropsy patients supports the concept that the postnatal fibroelastotic thickening of the foramen ovale valve endocardial tissue is a nonspecific response of the living to increased mural tension. In changing from a passive structure in the transseptal bloodstream into a barrier of the orifice of the foramen ovale, the valve becomes subject to the tension that acts on the atrial wall. The thickness of the valve increases slowly until birth, abruptly thickens in the newborn period and then returns to a pattern of slow, steady increase.

QUICK QUIZ

Fig. 1

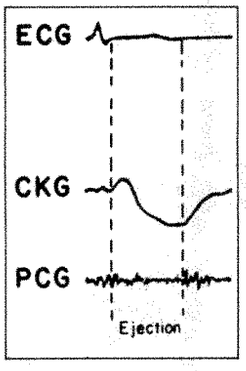

Fig. 2

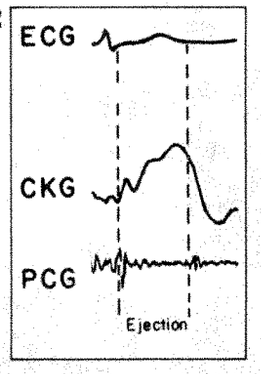

Fig. 3

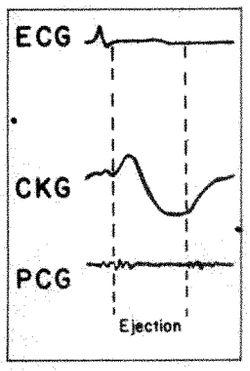

Fig. 4

I. Figure 1 is a pre-stress CKG™ (Cardiokymograph) tracing of the left ventricle (V3 position), it demonstrates:*

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

II. Figure 2 is a two minute post-stress CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

III. Figure 3 is a thirty minute post-stress resting CKG (Cardiokymograph) tracing of the left ventricle (V3 position), on the same patient, demonstrating:

- ☐ A. normal systolic inward motion
- ☐ B. midsystolic bulging
- ☐ C. holosystolic outward motion
- ☐ D. other

IV. Figures 1, 2 and 3, taken together, demonstrate:

- ☐ A. stress induced ventricular wall motion abnormalities consistent with ischemia
- ☐ B. normal ventricular wall motion

V. According to recently published(1) data, the CKG (Cardiokymograph) stress test is:

- ☐ A. 98% sensitive—98% specific
- ☐ B. 59% sensitive—69% specific
- ☐ C. 74% sensitive—95% specific
- ☐ D. 40% sensitive—60% specific

VI. Figure 4 is a photograph of:

- ☐ A. CKG/700 (Cardiokymograph)
- ☐ B. a noninvasive device that provides an analog representation of wall motion
- ☐ C. a low cost, simple device to be used in conjunction with stress testing to enhance diagnostic accuracy
- ☐ D. all of the above

Here are practical solutions to crucial problems in

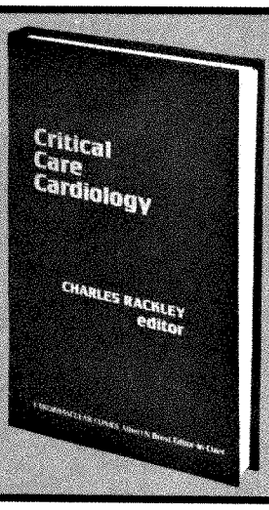
CRITICAL CARE CARDIOLOGY

Cardiovascular Clinics, Volume 11, Number 3

Guest Editor: **Charles E. Rackley, MD,** Professor of Medicine, Division of Cardiology, University of Alabama School of Medicine, Birmingham, Alabama.

For the diagnosis and clinical manegement of acute cardiac and circulatory disorders in the critical or intensive care medical center, you will find no better guide than this excellent new book. A superb team of eminent clinicians share with you their proven lifesaving techniques, such as:

- recent developments in radionuclide scans,
- hemodynamic monitoring,
- assessment of myocardial infarction size,
- intra-aortic balloon counterpulsation,



- computerized postoperative surgical management,
- advances in treatment of myocardial infarction, arrhythmias, heart failure, shock, bacterial endocarditis, and severe hypertension,
- surgical approach to emergency coronary revascularization, aortic dissection, and complications of acute myocardial infarction.

Cardiologists, internists, and cardiovascular surgeons will find this compilation of major life-saving developments in cardiovascular medicine an essential addition to their reference library.

227 pages. Illustrated. $40.00. January 1981. Order #7242-X.

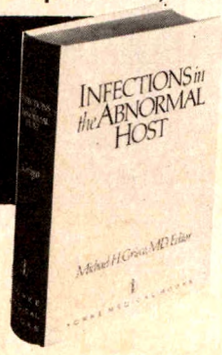
INFECTIONS IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

Norpace®
(disopyramide phosphate)

Before prescribing Norpace (disopyramide phosphate), please consult current complete prescribing information, a summary of which follows: ***Indications:*** *For suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.* ***Contraindications:*** *Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.* ***Warnings: Norpace may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and discontinuation of Norpace considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace with other Type 1 antiarrhythmic agents should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken.*** ***Precautions:*** *Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood.* ***Norpace has been reported to stimulate contractions of the pregnant uterus.*** *Use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown. Safety and effectiveness of Norpace in children have not been established.* ***Adverse Reactions:*** *Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported.* ***Dosage and Administration:*** *Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients less than 110 pounds (50 kg) the recommended dosage is 100 mg every six hours. If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg every six hours, with subsequent dosage adjustments made gradually with close monitoring.* ***See current complete prescribing information for dosage recommendations. How Supplied:*** *Capsules containing 100 mg or 150 mg of disopyramide base.*

SEARLE *Searle Laboratories*
Division of Searle Pharmaceuticals Inc.
Box 5110, Chicago, Illinois 60680

The answer is....

Norpace® (disopyramide phosphate)

*in specific ventricular arrhythmias**

Efficacy comparable with quinidine

Proved with Holter recordings in double-blind clinical trials

More compatible with digoxin

Norpace, unlike quinidine, does not cause elevation of serum digoxin levels[2]

Better tolerated than quinidine

One fourth the dropout rate vs quinidine in double-blind clinical trials

Outstanding patient acceptance

- *Easily individualized dosing*
- *Usually well tolerated – even during long-term administration*

As with any antiarrhythmic drug, serious adverse reactions may occur in patients taking Norpace. Please see the facing page for a brief summary of prescribing information.

Norpace®

3.5 million patient-months of experience

97.5% HOLTER DETECTION ACCURACY

HOLTER II/AUTOSCAN

The Accuracy

Holter II/Autoscan is the ONLY Holter System that computer analyzes every ECG complex on a "real time", beat-by-beat basis, DURING the actual patient monitoring period. Every ECG complex is compared to that patient's averaged updated "normal" complex for changes in rate, rhythm, morphology and signal quality (artifact). Since this computer analysis is performed at "real-time" rather than 60, 120, 240, or 480 times normal, Holter II/Autoscan has achieved a level of detection accuracy and ease of operation not possible with any other Holter system. Clinical Studies* have demonstrated an average of 97.5% quantitative detection accuracy and 100% qualitative detection accuracy. And, since the tape you receive from the patient is completely "pre-analyzed", only 6 minutes of operator time is required to process the tape.

The Challenge

Holter manufacturers' advertising often contains claims of increased accuracy of their respective systems. However, data to support these claims are rarely, if ever, provided. Now IMC has taken the lead with the only validated Holter system on the market.

WE CHALLENGE YOU TO COMPARE HOLTER II/AUTOSCAN:

- **TO YOUR PRESENT HOLTER SYSTEM**
- **TO ANY HOLTER SYSTEM YOU ARE CONSIDERING FOR PURCHASE**

If you want to know what you have been (or will be) missing: stop by IMC's booth at the AHA Meeting or check the system you want to compare on this ad and send it along with your name and address to IMC, (or call our toll free phone number). We will provide you a patient Holter tape compatible with the system you indicate, a hand count of every abnormal complex classified by type of anomaly, and the detection accuracy of the Holter II/Autoscan System for that tape. We know you'll find the results to be enlightening!

REPORTS ON THERAPY

95 Improved Exercise Performance in Persons With Stable Angina Pectoris Receiving Diltiazem

KENNETH F. HOSSACK, ROBERT A. BRUCE with the technical assistance of SHIRLEY TRIMBLE and FUSAKO KUSUMI

In a clinically random, double-blind study of 10 patients with stable angina pectoris, the use of diltiazem, a calcium antagonist drug, in a dosage of 240 mg/day increased the patients' duration of exercise on a treadmill, prolonged their time of exercise to the onset of angina and eliminated their angina as the symptom for limiting exercise. The drug reduced the heart rate at rest and at submaximal exertion, but produced no significant change in maximal heart rate during exercise. During submaximal exercise there was a reduction in diastolic blood pressure but not in systolic pressure. Five of the six patients who continued to take the drug maintained or improved their exercise performance on a follow-up study 8 to 12 months later.

102 Effect of Intravenous and Intracoronary Nitroglycerin on Left Ventricular Wall Motion and Perfusion in Patients with Coronary Artery Disease

M. PATRICIA McEWAN, NEIL D. BERMAN, JOHN E. MORCH, DAVID H. FEIGLIN and PETER R. McLAUGHLIN

In 30 patients with significant left anterior descending coronary artery disease and resting anterior wall asynergy, intravenous and intracoronary nitroglycerin may reverse wall motion asynergy and produce favorable or unfavorable changes in perfusion. Both systemic and intracoronary nitroglycerin improved wall motion of hypokinetic ventricular segments in nearly half of the patients studied. Afterload reduction by either intravenous or intracoronary nitroglycerin appeared to be the common mechanism that improved wall motion. These data suggest that systemic effects of nitroglycerin are the most important in reversing asynergy. A variable response on left ventricular preload, with both decreases and increases in end-diastolic volume, was observed. The ejection fraction increased significantly in patients with reversible asynergy after both intravenous and intracoronary injections of nitroglycerin.

109 Hemodynamic Effects of Molsidomine at Rest and During Submaximal and Maximal Exercise in Patients With Coronary Artery Disease Limited by Exertional Angina Pectoris

JEAN-MARIE R. DETRY, JACQUES MELIN, LUCIEN A. BRASSEUR, JACQUES COSYNS and MICHEL F. ROUSSEAU

Molsidomine, a new antianginal drug studied in 10 patients with coronary artery disease and exertional angina pectoris, increased heart rate and decreased cardiac output and mean systemic and pulmonary arterial pressures at rest and during submaximal exercise. Its hemodynamic mechanisms of action that improved exercise tolerance in 60 percent of the patients resemble those of nitrates and include a decrease in venous and arterial tone that lasts 5 to 8 hours after oral, sublingual or intravenous administration. The prevention of angina pectoris in 60 percent of the patients after molsidomine was attended by a marked decrease in the mean pulmonary arterial pressure, no change in cardiac output and lower mean arterial pressure and systemic vascular resistance.

116 Hemodynamics at Rest and During Exercise After Oral Hydralazine in Patients With Cor Pulmonale

LEWIS J. RUBIN and ROBERT H. PETER

This hemodynamic study of 12 patients with chronic cor pulmonale indicates that the lung vascular bed in some patients responds to oral hydralazine with a reduction in pulmonary resistance and an increase in cardiac output both at rest and during exercise. During exercise, the stroke volume increased by 30 percent. Mean systemic blood pressure and heart rate were not appreciably changed. These 12 patients with parenchymal lung disease and pulmonary hypertension showed an increased oxygen delivery to the tissue at a lower right ventricular afterload both at rest and during exercise after being treated with oral hydralazine. No adverse effects limited the drug's use. The use of effective vasodilators may prove helpful in the management of cor pulmonale, although it is not known if they will alter the clinical course of patients with this condition.

THE IMAGE QUALITY IS EVERYTHING YOU'D EXPECT FROM HEWLETT-PACKARD

Compact, cart-mounted mobile system is ideal for the cardiology lab as well as coronary care units.

Now you can get a full-featured, real time, phased array, two-dimensional scanner that offers meaningful technological advances in almost every area.

It's the real time scanner for echocardiography from Hewlett-Packard. Incorporating a small 64-element array transducer, innovations in signal processing, microcomputer-based circuitry and a new digital scan converter, the HP system not only provides superior image quality, it does it at a price

Small, lightweight, handheld transducer minimizes operator fatigue and fits easily in difficult

that compares favorably to conventional mechanical scanners.

Superb resolution for accurate diagnosis.

The HP Ultrasound Imaging System provides extraordinarily high resolution images at all depths throughout the field of view. Its wide aperture, small electronic array transducer and automatic focusing technique give you extremely accurate images—even in areas near the transducer and deep in the body. And since the entire field of view is in focus at all times, you can see shallow as well as deep structures in the same picture. The compact, lightweight transducer fits in intercostal spaces and enhances the scanning of the heart.

Built-in self-test capability assures the operator that everything is functioning properly.

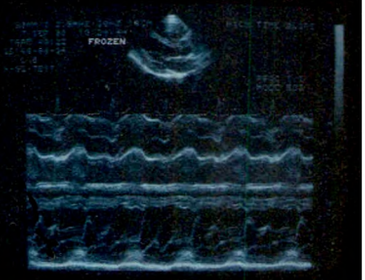
A new method of digital scan conversion eliminates radial scan lines, moire patterns and blocky digital artifacts, and results in an accurate image. A total of 30 shades of gray can be processed, so small variations in tissue density can be distinguished.

Quantitative analysis on both the M-mode and two-dimensional image is accomplished by an electronic cursor.

The wide dynamic range of the system's circuitry produces a sharp image, while reducing background noise and clutter. The system's high-resolution, high-speed (twice the conventional TV rate) display gives you an easy-to-see, taped and replayed on standard video equipment.

Simple, centralized controls for easy operation.

With the HP scanner, you not only get superior image quality, you get it quickly and easily. All major con-



M-mode is easily visualized on the same screen as the two-dimensional sector.

trols are logically located in one central area. You can scan patient after patient with a minimum of control adjustments. The HP scanner even provides a built-in self-test capability, so you know that everything is functioning properly.

All this and more, for less.

While the HP scanner delivers exceptional image quality and easy operation, it doesn't compromise features. It offers quantitative analysis capabilities, ECG triggering, and "freeze-frame." You can view the sector scan and the M-mode display on the same screen simultaneously. In addition, the dual M-mode display lets you analyze two areas of the heart at the same time.

For more information on this full-featured, surprisingly affordable HP Model 77020A Ultrasound Imaging System for echocardiography, call your local Hewlett-Packard sales office, or write: Wayne Wager, Hewlett-Packard, 175 Wyman

123 **Clinical Pharmacology and Antiarrhythmic Efficacy of N-Acetylprocainamide**

ROGER A. WINKLE, PATRICE JAILLON, ROBERT E. KATES and FLORA PETERS

N-Acetylprocainamide (NAPA), the major metabolite of procainamide, suppressed chronic ventricular ectopic complexes without adverse effects in only a minority of the 11 patients with chronic ventricular arrhythmias. The investigators were able to achieve 90 percent suppression of ventricular ectopic complexes in only 2 of 11 patients. Several patients unsuccessfully treated with NAPA have subsequently had arrhythmias successfully suppressed with other new antiarrhythmic compounds. Adverse effects included an allergic rash in one patient, gastrointestinal symptoms in seven patients and visual symptoms in four patients at plasma concentrations as low as 6.9 mg/ml. This study also demonstrated that the drug differs electrophysiologically from procainamide, obeys linear pharmacokinetics over the clinically tolerated range of oral doses, and its antiarrhythmic action may have little relation with the antiarrhythmic response observed during long-term therapy with procainamide. The ultimate role of NAPA remains to be defined.

131 **Mexiletine for Refractory-Ventricular Arrhythmias: Results Using Serial Electrophysiologic Testing**

JOHN P. DiMARCO, HASAN GARAN and JEREMY N. RUSKIN

The administration of mexiletine during serial drug testing to 35 patients with electrically inducible ventricular arrhythmias and to 6 patients with recurrent ventricular tachycardia that could not be induced or terminated by programmed cardiac stimulation demonstrates that the drug provides well tolerated effective prophylaxis against recurrent ventricular arrhythmias in a significant proportion (42 percent) of patients resistant to conventional antiarrhythmic drugs. All patients had arrhythmias resistant to all conventionally available agents. Severe adverse neurologic effects (dysphagia, ataxia and disabling tremor) occurred early during mexiletine therapy in 3 patients, but none occurred in the 24 patients discharged on long-term therapy. The administration of mexiletine was discontinued in four patients who had spontaneous ventricular tachycardia within 48 hours after the start of mexiletine therapy. Mexiletine is a promising new antiarrhythmic drug capable of suppressing ventricular arrhythmias resistant to conventionally available drugs. Electrically induced tachycardias not inducible by programmed stimulation seem most likely to respond favorably.

139 **Electrophysiologic Effects of Ouabain in Patients With Preexcitation and Circus Movement Tachycardia**

RAMESH C. DHINGRA, EDWIN V. PALILEO, BORIS STRASBERG, STEVEN SWIRYN, ROBERT BAUERNFEIND, CHRISTOPHER WYNDHAM and KENNETH M. ROSEN

Because intravenously administered ouabain did not significantly affect anterograde or retrograde anomalous pathway refractoriness in 19 patients with an anomalous conduction pathway, and did not interfere with induction of tachycardia in most patients with preexcitation, use of oral glycosides alone appears to be of limited value in patients with preexcitation and recurrent supraventricular tachycardia. In this study, sustained atrioventricular (A-V) reentrant paroxysmal supraventricular tachycardia was inducible in all 19 patients before and in 17 patients (89 percent) after ouabain. Intravenously administered ouabain significantly increased the cycle length of induced tachycardia by depressing A-V nodal conduction, and tachycardia could not be induced in two patients because of this increased A-V nodal refractoriness. The lack of significant effect of digitalis on anomalous pathway refractoriness coupled with a possible increase in ventricular vulnerability to ventricular fibrillation suggests that this agent would be dangerous in patients with paroxysmal atrial fibrillation complicating preexcitation with a short anomalous pathway.

REVIEWS

145 **Observations on Detecting Left Ventricular Thrombus With Two Dimensional Echocardiography: Emphasis on Avoidance of False Positive Diagnosis**

RICHARD W. ASINGER, FRANK L. MIKELL, BIM SHARMA, MORRISON HODGES with the technical assistance of LILLIAN MICHAUD, JOE ELSPERGER, DARCIE BASS and KIM KARLSON

Two dimensional echocardiography can potentially detect left ventricular thrombus before embolization and make it possible to institute appropriate therapy in patients after infarction and to prevent or decrease the incidence of embolization. In this series of 2,657 consecutive two dimensional echocardiographic studies, 41 patients had echocardiographic findings highly suggestive (n = 25) or characteristic (n = 16) of left ventricular thrombus. In seven patients, left ventriculography demonstrated apical filling defects consistent with thrombus within 1 week of the two dimensional echocardiogram. Six patients had a surgical procedure that confirmed or supported the echocardiographic diagnosis of left ventricular thrombus. All patients had wall motion abnormalities adjacent to their thrombus. These results indicated that two dimensional echocardiography allows detection of left ventricular thrombi that might not be clinically manifest or detected by other available methods. A practical grading scale is presented that indicates the index of suspicion for left ventricular thrombus and minimizes false positive examinations.

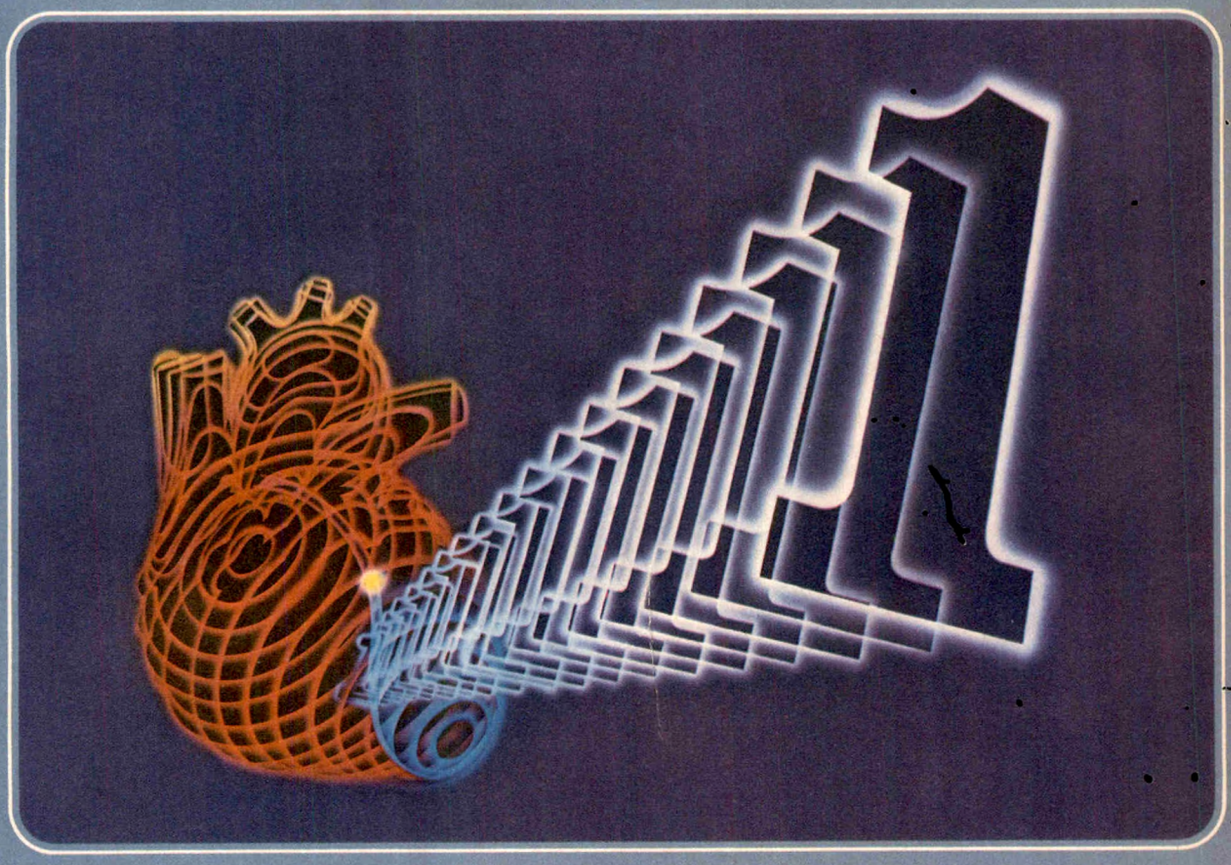
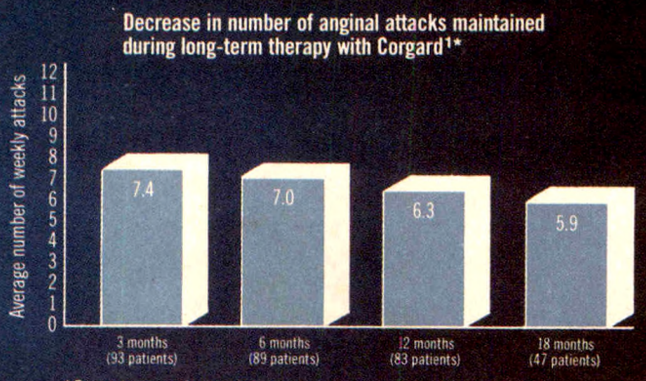
CORGARD®
nadolol tablets



The first and only beta-blocker with once-a-day dosage

In the treatment of angina pectoris

SQUIBB



*Seventeen patients also received long-acting nitrates and/or dipyridamole at some time during the long-term therapy period.

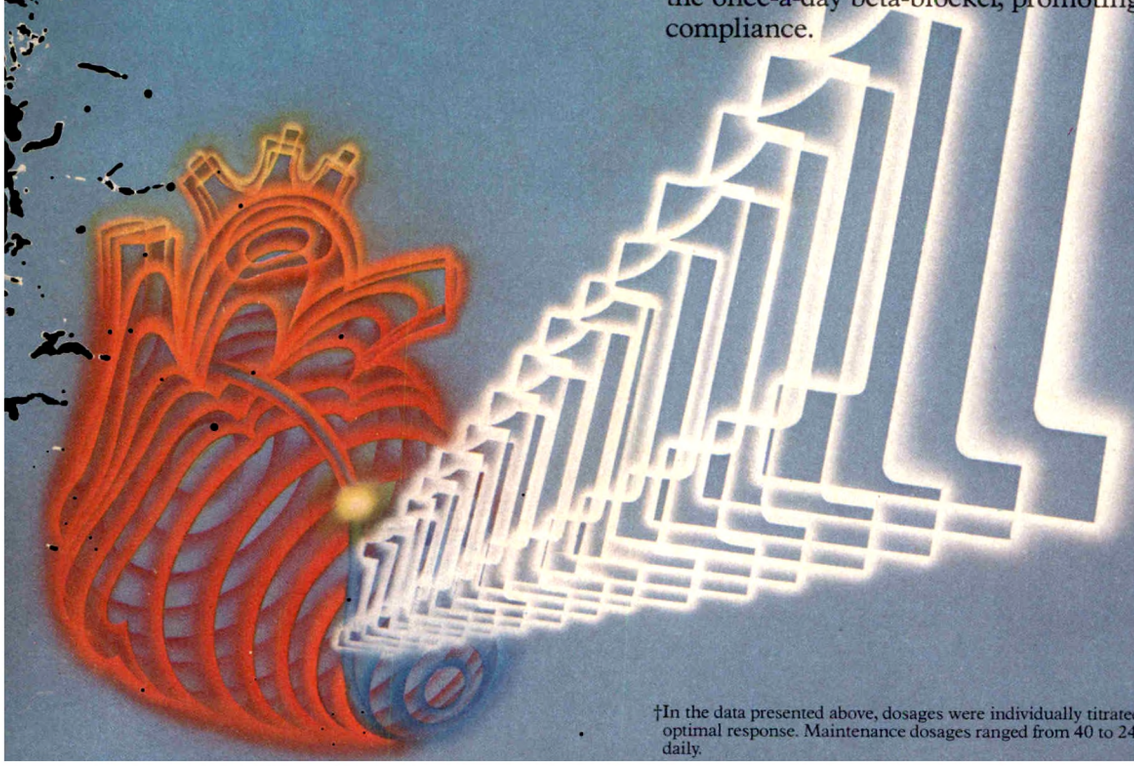
CORGARD® [nadolol tablets]:

Once-a-day, everyday, Corgard offers round-the-clock protection

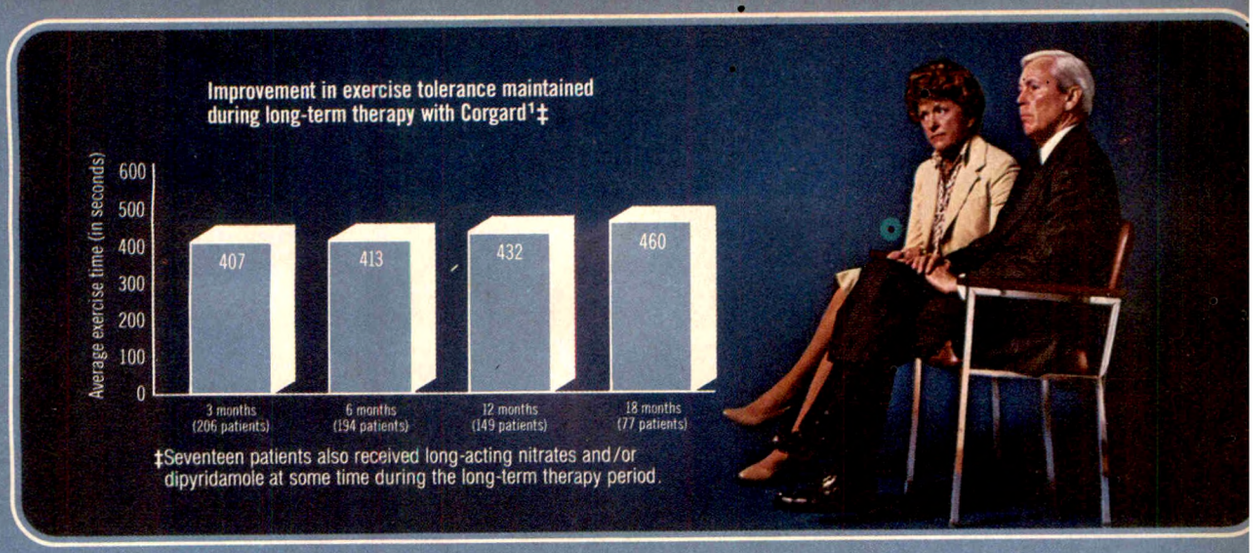
A single daily dose of Corgard offers prophylaxis in angina pectoris, helping to protect the patient all day and all night from painful attacks. And in extended clinical studies, the efficacy of Corgard — as demonstrated by a decreased rate of anginal attacks and an increase in exercise tolerance — was maintained.[1]

Once-a-day, everyday, Corgard decreases the frequency of anginal attacks

Corgard taken just once daily offers round-the-clock protection from angina pain. In one short-term study, Corgard, once a day, decreased the average number of anginal attacks per week in 115 patients with angina, from 13.6 pretherapy to 6.4 at the end of 14 weeks of therapy, a mean decrease of 59%.[1†] In 19% of the 115 patients, anginal attacks were completely eliminated. And the long half-life (20 to 24 hours) makes Corgard the once-a-day beta-blocker, promoting patient compliance.



†In the data presented above, dosages were individually titrated to achieve optimal response. Maintenance dosages ranged from 40 to 240 mg Corgard daily.



Effective control of angina pectoris

Once-a-day, everyday, Corgard increases exercise tolerance

Corgard allows the angina patient to do more. In 147 patients in the same short-term study as the one at left, Corgard, once a day, increased ergometry time by 25%, improving exercise tolerance from an average of 365 seconds pretherapy to 427 seconds at the end of 14 weeks of therapy.[1] In 21% of the 147 patients, the end point of exercise was fatigue rather than angina pain. And the single daily dose of Corgard can be taken at the patient's convenience, without regard to meals.

Once-a-day, everyday, Corgard decreases nitroglycerin usage[1]

Corgard blocks catecholamine influence on myocardial activity, decreases myocardial oxygen demand, and does not have a direct myocardial depressant effect.

Prescribe

CORGARD®

nadolol tablets

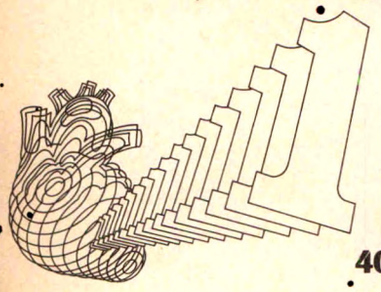
40 mg, 80 mg, 120 mg, and 160 mg tablets

The common-sense beta-blocker for angina pectoris

SQUIBB®

See next page for brief summa

The only once-a-day beta-blocker for both angina pectoris and hypertension



CORGARD®
nadolol tablets

40 mg, 80 mg, 120 mg, 160 mg scored tablets

CORGARD® TABLETS
Nadolol Tablets

DESCRIPTION: Corgard (nadolol) is a synthetic nonselective beta-adrenergic receptor blocking agent.

CONTRAINDICATIONS: Bronchial asthma, sinus bradycardia and greater than first degree conduction block, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure—Sympathetic stimulation may be a vital component supporting circulatory function in congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, they can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle. IN PATIENTS WITHOUT A HISTORY OF HEART FAILURE, continued use of beta-blockers can, in some cases, lead to cardiac failure; therefore, at first sign or symptom of heart failure, digitalize and/or give diuretics, and closely observe response, or discontinue nadolol (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal — Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronic use of nadolol, particularly in patients with ischemic heart disease, gradually reduce dosage over a 1- to 2-week period and carefully monitor the patient. Reinstitute nadolol promptly (at least temporarily) and take other measures appropriate for management of unstable angina if angina markedly worsens or acute coronary insufficiency develops. Warn patients not to interrupt or discontinue therapy without physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue nadolol therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema) — PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA-BLOCKERS. Administer nadolol with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery — Because beta-blockade impairs the ability of the heart to respond to reflex stimuli and may increase risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, withdraw beta-blockers well before surgery takes place. In emergency surgery, inform the anesthesiologist that the patient is on beta-blocker therapy. Use of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol can reverse the effects of nadolol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia — Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust dose of antidiabetic drugs.

Thyrotoxicosis — Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. To avoid abrupt withdrawal of beta-adrenergic blockade which might precipitate a thyroid storm, carefully manage patients suspected of developing thyrotoxicosis.

PRECAUTIONS: Impaired Hepatic or Renal Function — Use nadolol with caution in the presence of either of these conditions (see DOSAGE AND ADMINISTRATION section of package insert).

Information for Patients — Warn patients, especially those with evidence of coronary artery insufficiency, against interruption or discontinuation of nadolol without physician's advice. Although cardiac failure rarely occurs in properly selected patients, advise patients being treated with beta-adrenergic blocking agents to consult physician at first sign or symptom of impending failure.

Drug Interactions — Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. When treating patients with nadolol plus a catecholamine-depleting agent, carefully observe for evidence of hypotension and/or excessive bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility — In 1 to 2 years' oral toxicologic studies in mice, rats, and dogs, nadolol did not produce significant toxic effects. In 2-year oral carcinogenic studies in rats and mice, nadolol did not produce neoplastic, preneoplastic, or nonneoplastic pathologic lesions.

Pregnancy — In animal reproduction studies with nadolol, evidence of embryo- and fetotoxicity was found in rabbits (but not in rats or hamsters) at doses 5 to 10 times greater (on a mg/kg basis) than maximum indicated human dose; no teratogenic potential was seen in any of these species. There are no well-controlled studies in pregnant women; therefore, use nadolol in pregnant women only if potential benefit justifies potential risk to the fetus.

Nursing Mothers — It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when nadolol is administered to a nursing woman. Animal studies showed that nadolol is found in the milk of lactating rats.

Pediatric Use — Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient and have rarely required nadolol withdrawal.

Cardiovascular — Bradycardia with heart rates of less than 60 beats per minute occurs commonly, and heart rates below 40 beats per minute and/or symptomatic bradycardia were seen in about 2 of 100 patients. Symptoms of peripheral vascular insufficiency, usually of the Raynaud type, have occurred in approximately 2 of 100 patients. Cardiac failure, hypotension, and rhythm/conduction disturbances have each occurred in about 1 of 100 patients. Single instances of first degree and third degree heart block have been reported; intensification of AV block is a known effect of beta-blockers (see also CONTRAINDICATIONS, WARNINGS, and PRECAUTIONS). **Central Nervous System** — Dizziness or fatigue reported in approximately 2 of 100 patients; paresthesias, sedation, and change in behavior reported in approximately 6 of 1000 patients. **Respiratory** — Bronchospasm reported in approximately 1 of 1000 patients (see CONTRAINDICATIONS and WARNINGS). **Gastrointestinal** — Nausea, diarrhea, abdominal discomfort, constipation, vomiting, indigestion, anorexia, bloating, and flatulence each reported in 1 to 5 of 1000 patients. **Miscellaneous** — Each of the following reported in 1 to 5 of 1000 patients: rash; pruritus; headache; dry mouth, eyes, or skin; impotence or decreased libido; facial swelling; weight gain; slurred speech; cough; nasal stuffiness; sweating; tinnitus; blurred vision. Although relationship to drug usage is not clear, sleep disturbances have been reported. The oculomucocutaneous syndrome associated with practolol has not been reported with nadolol.

Potential Adverse Effects: Although other adverse effects reported with other beta-adrenergic blocking agents have not been reported with nadolol, they should be considered potential adverse effects of nadolol. **Central Nervous System** — reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place; short-term memory loss, emotional lability with slightly clouded sensorium; decreased performance on neuropsychometrics. **Gastrointestinal** — mesenteric arterial thrombosis; ischemic colitis. **Hematologic** — agranulocytosis; thrombocytopenic or nonthrombocytopenic purpura. **Allergic** — fever combined with aching and sore throat; laryngospasm; respiratory distress. **Miscellaneous** — reversible alopecia; Peyronie's disease; erythematous rash.

OVERDOSAGE: Nadolol can be removed from the general circulation by hemodialysis. In addition to gastric lavage, employ the following measures as appropriate. In determining duration of corrective therapy, take note of long duration of effect of nadolol.

Excessive Bradycardia — Administer atropine (0.25 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure — Administer a digitalis glycoside and diuretic. It has been reported that glucagon may also be useful in this situation.

Hypotension — Administer vasopressors, e.g., epinephrine or levarterenol. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm — Administer a $beta_2$-stimulating agent and/or a theophylline derivative.

DOSAGE: For all patients, DOSAGE MUST BE INDIVIDUALIZED.

For **angina pectoris,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments at 3 to 7 day intervals until optimum clinical response or pronounced slowing of the heart rate; usual maintenance dose is 80 to 240 mg q.d. (most patients respond to 160 mg or less daily). If treatment is to be discontinued, reduce dosage gradually over a period of 1 to 2 weeks (see WARNINGS).

For **hypertension,** usual initial dose is 40 mg q.d.; gradually increase in 40 to 80 mg increments until optimum blood pressure reduction is achieved; usual maintenance dose is 80 to 320 mg q.d. (rarely, doses up to 640 mg may be needed).

Patients with renal failure require adjustment in dosing interval — see package insert for dosage in these patients.

For full prescribing information, consult package insert.

HOW SUPPLIED: In scored tablets containing 40, 80, 120, or 160 mg nadolol per tablet in bottles of 100 and 1000 tablets and in Unimatic® single-dose packs of 100 tablets.

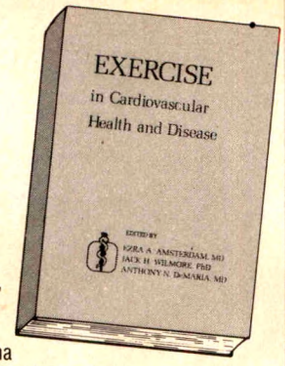
For every professional with an interest in Exercise and the Heart.

EXERCISE in Cardiovascular Health and Disease



Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS. $33.00

This comprehensive work covers every aspect of exercise and its role in **Diagnosis, Treatment,** and **Prevention** of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

"The list of contributors bespeaks its authority: outstanding physicians in cardiovascular medicine and distinguished physical educators . . . No serious student or practitioner in the field would wish to be without this remarkably thorough account . . ."

David H. Spodick, MD, St. Vincent Hospital, Worcester, Mass. in ***The Journal of the American Medical Assoc.,*** *June 16, 1978, Vol 239, No. 24*

"Many areas in this field which have not as yet been addressed under one cover and a few rather unique ones are mentioned . . . an important synthesis of our current knowledge in the field."

Harold T. Mankin, MD, Division of Cardiovascular Diseases and Internal Medicine, ***Mayo Clinic Proceedings,*** *May 1978*

Yorke Medical Books 666 Fifth Avenue, New York, N.Y. 10103 AJC 1/81

Please send me a copy of EXERCISE in Cardiovascular Health and Disease at $33.00. I may use the book for 30 days and if not completely satisfied, return it for full refund or credit.

☐ Bill me, plus cost of shipping.
☐ Payment enclosed, publisher pays shipping.

SEMINAR ON CALCIUM CHANNEL BLOCKERS—PART II

57 **Therapy of Coronary Vasoconstriction in Patients With Coronary Artery Disease**

STEPHEN GUNTHER, JAMES E. MULLER, GILBERT H. MUDGE, Jr. and WILLIAM GROSSMAN

Nifedipine, 10 mg given buccally, prevented the increase in coronary vascular resistance during the cold pressor test in 10 of 10 patients with coronary artery disease. The response in five patients treated with placebo remained unchanged. This dose had no effect on systemic hemodynamics or myocardial oxygen consumption either at rest or during the cold pressor test. At this dose, nifedipine appeared to exert a selective, antivasoconstrictive effect on the coronary circulation and was well tolerated without side effects by all patients. Of the antianginal drugs, calcium antagonists appear to be most effective in preventing coronary vasoconstriction.

63 **Nifedipine in the Treatment of Unstable Angina, Coronary Spasm and Myocardial Ischemia**

PAUL G. HUGENHOLTZ, HERMAN R. MICHELS, PATRICK W. SERRUYS and RON W. BROWER

Intracoronary injection of nifedipine promptly reversed provoked or spontaneous coronary spasm in five of six patients studied in the cardiac catheterization laboratory. In other patients, intracoronary injection was associated with virtual cessation of local mechanical cardiac action and thinning of the ventricular wall during systole, which indicated a specific inhibitory action on contractile energy expenditure in the presence of increased coronary flow. Coronary arteriography demonstrated severe atherosclerotic coronary artery disease in 14 of 20 patients who responded promptly to nifedipine. These and other results in 31 patients with symptomatic unstable angina led the investigators to recommend that nifedipine should be added to beta adrenergic blockade therapy if the latter does not appear immediately effective. This combination has not been shown to cause adverse hemodynamic effects.

74 **Treatment of Prinzmetal's Variant Angina. Role of Medical Treatment With Nifedipine and Surgical Coronary Revascularization Combined With Plexectomy**

MICHEL E. BERTRAND, JEAN M. LABLANCHE and PIERRE Y. TILMANT

This study suggests the following emerging strategy for the treatment of Prinzmetal's angina: Intravenous, or preferably intracoronary, injection of nitroglycerin is the basic therapy for spasm that occurs during coronary arteriography (although intracoronary injection of 0.2 mg of nifedipine may be beneficial); coronary arterial bypass grafting combined with partial denervation of the heart for patients with fixed arteriosclerotic lesions and superimposed spasm; and calcium antagonists for patients with angiographically normal coronary arteries. In these 70 patients with Prinzmetal's angina 29 percent had angiographically normal coronary arteries and the remainder had fixed atherosclerotic lesions.

Ergonovine Testing to Detect Spontaneous Remissions of Variant Angina During Long-Term Treatment With Calcium Antagonist Drugs

DAVID D. WATERS, JADWIGA SZLACHCIC, PIERRE THEROUX, FRANZ DAUWE and HENRY F. MIZGALA

In this subgroup of 22 patients with variant angina and an initially positive ergonovine test who had responded well to calcium antagonist drugs, all were free from anginal attacks while taking the drugs. After medication was discontinued, 12 patients did not have angina or S-T segment shifts during a second ergonovine test to a maximal dose of 0.4 mg. All 12 also remained free of variant anginal attacks without these drugs, 4.2 ± 2.9 months later. The patients whose tests reverted to negative could not be differentiated by other clinical variables from those whose tests remained positive. These results indicate that ergonovine testing is helpful in identifying patients with variant angina in whom treatment with calcium antagonist drugs can probably be safely discontinued.

HISTORICAL MILESTONES

5 **The Frustrated Benevolance of "Dr. Anonymous"**

PAUL KLIGFIELD

This month's Milestone blows the cover of the mysterious Dr. Anonymous of Chester and provides the reader with examples of Dr. Heberden's skill as a masterful physician and English writer. For a real learning experience, try writing your own short description of angina pectoris and then compare it with Heberden's.

SPECIAL DEPARTMENTS

8 **Books Received**

9 **American College of Cardiology News**

You May Be Mis-Diagnosing Your Holter Patients.

The incompleteness of Holter scan reports with unverifiable numbers and trends are the reasons. Less than 1% of the Holter ECG data is normally presented for your diagnosis. What happened the other 99% of the time?

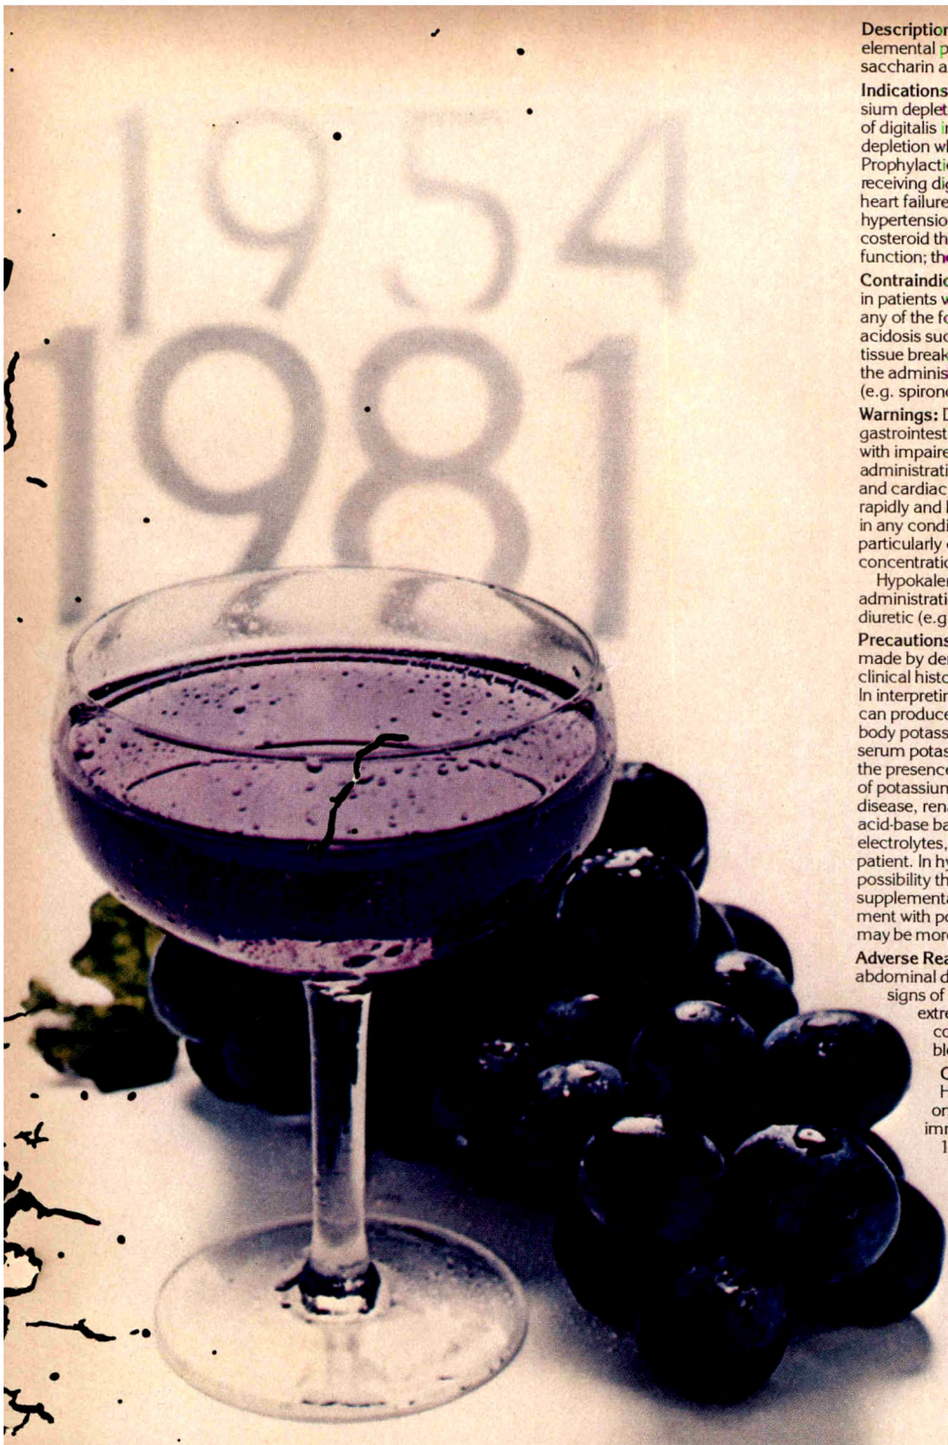
1979 brought a breakthrough in Holter monitoring. The development of micro-computer controlled fiberoptics made it possible to print every ECG complex into a textbook format, providing twenty-four, hourly pages of ECG data.

No matter who the operator, the report is identical every time, and only takes three minutes to generate. Plus, this report is faster and easier to read than that of conventional Holter equipment.
The major difference is "Assurance".

The product is The Eliminator™ by AdvanceMed, now a part of American Hospital Supply Corporation. The Eliminator is the first to offer 100% accurate ECG data and is available at half the price of average Holter equipment.

You owe it to yourself and to your patients to see The Eliminator. Since it is compatible with most Holter recording systems, call or write and we'll run one of your tapes.
You May Be Surprised To See What You Are Missing!

American Edwards / AdvanceMed, 1923 SE Main Street, Irvine, California 92714, (714) 751-1824. (800) 854-8081.



Description: Each 15 ml (tablespoonful) supplies 20 mEq of elemental potassium (as potassium gluconate, 4.68 g) with saccharin and aromatics. Alcohol 5%.

Indications: Kaon Elixir is indicated for the treatment of potassium depletion in patients with hypokalemia, for the treatment of digitalis intoxication, and for the prevention of potassium depletion when the dietary intake of potassium is inadequate. Prophylactic administration may be indicated in patients receiving digitalis and diuretics for the treatment of congestive heart failure; hepatic cirrhosis with ascites; patients with hypertension on long-term diuretic therapy; patients on corticosteroid therapy; hyperaldosteronism states with normal renal function; the nephrotic syndrome; and certain diarrheal states.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g. spironolactone, triamterene).

Warnings: Do not administer full strength. Kaon Elixir may cause gastrointestinal irritation if administered undiluted. In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in any condition which impairs potassium excretion requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g. spironolactone or triamterene).

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient. In hypokalemic states, hypochloremic alkalosis is a possibility that may require chloride as well as potassium supplementation. In these circumstances, potassium replacement with potassium chloride (e.g. Kaochlor 10% Liquid, W-T) may be more advantageous than with other potassium salts.

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort have been reported. The symptoms and signs of potassium intoxication include paresthesias of the extremities, flaccid paralysis, listlessness, mental confusion, weakness and heaviness of the legs, fall in blood pressure, cardiac arrhythmias, and heart block.

Overdosage and Treatment of Hyperkalemia: Hyperkalemia can occur from overdosage or during one of several medical conditions. It should be treated immediately by one or more of the following: 1) Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-20 units of crystalline insulin per 1,000 ml. 2) administration of sodium or ammonium cycle exchange resins orally or as retention enemas; 3) hemodialysis or peritoneal dialysis; 4) elimination of potassium containing foods. Caution: Digitalis toxicity can occur if the serum potassium is lowered too rapidly.

How Supplied: Pints and gallons in Grape and Lemon-Lime flavors; 15 ml Stat-Pak and 4 fl. oz. in Grape flavor only.

Vintage potassium that's always in good taste.

Kaon® Elixir
(potassium gluconate)
20 mEq per 15 ml

Pleasant tasting grape or lemon-lime flavors
Prescribed with confidence for 26 years

- Well accepted—good patient tolerance
- One tbsp. in 1 oz or more of water supplies 20 mEq potassium (as gluconate)

dria Laboratories Inc., Columbus, Ohio 43215

LANOXIN®
(DIGOXIN)
TABLETS
0.125 mg Scored (yellow), I.D. Imprint Y3B
0.25 mg Scored (white), I.D. Imprint X3A
0.5 mg Scored (green), I.D. Imprint T9A

LANOXIN®
(DIGOXIN)
ELIXIR PEDIATRIC
50 mcg (0.05 mg) per cc

INDICATIONS:

1. Congestive heart failure: Congestive heart failure, all degrees, is the primary indication. The increased cardiac output due to digoxin results in diuresis and general amelioration of the disturbances characteristic of right (venous congestion, edema) and left (dyspnea, orthopnea, cardiac asthma) heart failure.

Digoxin, generally, is most effective in "low output" failure and less effective in "high output" (bronchopulmonary insufficiency, infection, hyperthyroidism) heart failure.

Digoxin should be continued after heart failure is abolished unless some known precipitating factor is corrected.

2. Atrial fibrillation: Atrial fibrillation, especially when the ventricular rate is elevated. Digoxin rapidly reduces ventricular rates and eliminates the pulse deficit. Palpitation, precordial distress or weakness are relieved and any concomitant congestive failure ameliorated. Digoxin should be continued in doses necessary to maintain the desired ventricular rate and other clinical effects.

3. Atrial flutter: Digoxin slows the heart and regular sinus rhythm may appear. Frequently the flutter is converted to atrial fibrillation with a slow ventricular rate. Stopping digoxin at this point may be followed by restoration of sinus rhythm, especially if the flutter was of the paroxysmal type. It is preferable, however, to continue digoxin if failure ensues or if atrial flutter is a frequent occurrence.

4. Paroxysmal atrial tachycardia: Oral digoxin may be used, especially if the condition is resistant to lesser measures. Depending on the urgency, a more rapid acting parenteral preparation may be preferable to initiate digitalization, although if heart failure has ensued or paroxysms recur frequently, digoxin should be maintained by oral administration.

Digoxin is not indicated in sinus tachycardia unless due to heart failure.

5. Cardiogenic shock: The drug is often employed, especially when the condition is accompanied by pulmonary edema. Digoxin seems to affect adversely shock due to septicemia from gram-negative bacteria.

CONTRAINDICATIONS: The presence of toxic effects (see ADVERSE REACTIONS section) induced by any digitalis preparation is a contraindication to all of the glycosides.

Allergy, though rare, does occur. It may not extend to all preparations, and another may be tried.

Ventricular fibrillation.

WARNINGS:

> Digitalis alone or with other drugs has been promoted for use in the treatment of obesity. This use of digoxin or other digitalis glycosides is unwarranted. Moreover, since they may cause potentially fatal arrhythmias or other adverse effects, the use of these drugs in the treatment of obesity is dangerous.

Many of the arrhythmias for which digoxin is advised closely resemble those reflecting digoxin intoxication. If the possibility of digoxin intoxication cannot be excluded, cardiac glycosides should be temporarily withheld if permitted by the clinical situation.

The patient with congestive heart failure may complain of nausea and vomiting. These symptoms may also be indications of digoxin intoxication. A clinical determination of the cause of these symptoms must be attempted before further drug administration.

Patients with renal insufficiency require smaller than usual doses of digoxin. Newborn infants display considerable variability in their tolerance to digoxin, depending on their degree of maturity.

Premature and immature infants are particularly sensitive, and dosage must be reduced and digitalization should be even more individualized and cautiously approached than in more mature infants. Impaired renal function must also be carefully taken into consideration.

Congestive heart failure accompanying acute glomerulonephritis requires extreme care in digitalization. A relatively low total dose administered in divided doses and concomitant use of antihypertensive drugs has been recommended. ECG monitoring is essential. Digoxin should be discontinued as soon as possible.

Patients with idiopathic hypertrophic subaortic stenosis must be managed extremely carefully. Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Patients with rheumatic carditis, especially when severe, are unusually sensitive to digoxin and prone to disturbances of rhythm. If heart failure develops, digitalization may be initiated with relatively low doses; then it can be cautiously increased until a beneficial effect is obtained. If a therapeutic trial does not result in improvement, the drug should be considered ineffective and be discontinued.

Note: Digitalis glycosides are an important cause of accidental poisoning in children.

PRECAUTIONS: Atrial arrhythmias associated with hypermetabolic states are particularly resistant to digoxin treatment. Care must be taken to avoid digoxin toxicity if digoxin is used to help the arrhythmia.

Digoxin is not indicated for the treatment of ventricular tachycardia unless congestive heart failure supervenes after a protracted episode not itself due to digoxin.

Potassium depletion sensitizes the myocardium to digoxin and toxicity may develop even with usual dosage. Hypokalemia may also alter the rate of onset and intensity of the positive inotropic effect of digoxin. Therefore, it is desirable to maintain normal serum potassium levels in patients being treated with digoxin.

Potassium wastage may result from diuretic or corticosteroid therapy, hemodialysis, and from suction of gastrointestinal secretions. It may accompany malnutrition, diarrhea, prolonged vomiting, old age, and long-standing congestive heart failure. In general, rapid changes in serum potassium or other electrolytes are to be avoided, and intravenous treatment with potassium should be reserved only for special circumstances as described below (see TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGES section).

Patients with acute myocardial infarction, severe pulmonary disease, or far advanced heart failure may be more sensitive to digoxin and more prone to disturbances of rhythm.

Calcium affects contractility and excitability of the heart in a manner similar to that of digoxin. Calcium may produce serious arrhythmias in digitalized patients.

In myxedema, the digoxin requirements are less because excretion rate is decreased and blood levels are significantly higher.

In incomplete A-V block, especially in patients subject to Stokes-Adams attacks, advanced or complete heart block may develop if digoxin is given. Heart failure in these patients can usually be controlled by other measures and by increasing the heart rate.

Patients with chronic constrictive pericarditis may respond unfavorably to digoxin.

Patients with idiopathic hypertrophic subaortic stenosis must be managed extremely carefully. Unless cardiac failure is severe, it is doubtful whether digoxin should be employed.

Renal insufficiency delays the excretion of digoxin and dosage must be adjusted accordingly in patients with renal disease. Note: This applies also to potassium administration should it become necessary.

Electrical conversion of arrhythmias may require reduction of digoxin dosage.

Dosage must be carefully titrated and differences in the bioavailability of parenteral preparations, elixirs, and tablets should be taken into account when switching patients from one preparation to another.

Electrocardiographic monitoring may be necessary to avoid intoxication.

Premonitory signs of toxicity in the newborn are undue slowing of the sinus rate, sinoatrial arrest, and prolongation of PR interval.

ADVERSE REACTIONS:

Gynecomastia: Uncommon.

Overdose or toxic effects in adults:

Gastrointestinal: Anorexia, nausea, vomiting, diarrhea are the most common early symptoms of overdosages in the adult (but rarely conspicuous in infants). Uncontrolled heart failure may also produce such symptoms.

Central nervous system: Visual disturbances (blurred vision, yellow vision), headache, weakness, apathy.

Cardiac disturbances (arrhythmias): Ventricular premature beats are the most common, except in infants and young children. Paroxysmal and nonparoxysmal nodal rhythms, atrioventricular (interference) dissociation and paroxysmal atrial tachycardia (PAT) with block are also common arrhythmias due to digoxin overdosage.

Conduction disturbances: Excessive slowing of the pulse is a clinical sign of digoxin overdosage. Atrioventricular block of increasing degree may proceed to complete heart block. Note: The electrocardiogram is fundamental in determining the presence and nature of these cardiac toxic disturbances. Digoxin may also induce other changes (as of the ST segment), but these provide no measure of the degree of digitalization.

Overdose or toxic effects in children:

Toxic signs differ from the adult in a number of respects. Cardiac arrhythmias are the more reliable and frequent signs of toxicity.

Vomiting and diarrhea, neurologic and visual disturbances are rare as initial signs.

Premature ventricular systoles are rarely seen; nodal and atrial systoles are more frequent.

Atrial arrhythmias, atrial ectopic rhythms, and paroxysmal atrial tachycardia with A-V block particularly are more common manifestations of toxicity in children.

Ventricular arrhythmias are rare.

TREATMENT OF ARRHYTHMIAS PRODUCED BY OVERDOSAGE: Digoxin should be discontinued until all signs of toxicity are abolished. Discontinuation may be all that is necessary if toxic manifestations are not severe and appear after the time for peak effect of the drug.

Potassium salts are commonly used. Potassium chloride in divided oral doses totaling 4-6 grams for adults (see PEDIATRIC INFORMATION section for pediatric dosage) may be given provided renal function is adequate.

When correction of the arrhythmia is urgent and the serum potassium level is low or normal, potassium should be administered intravenously in a solution of 5 percent dextrose in water. A total of 40-100 milliequivalents (30 milliequivalents per 500 milliliters) is given at the rate of 20 milliequivalents per hour unless limited by pain due to local irritation.

Additional amounts may be given if the arrhythmia is uncontrolled and the potassium well tolerated.

Continuous electrocardiographic monitoring should be performed to watch for any evidence of potassium toxicity, e.g., peaking of T waves, and to observe the effect on the arrhythmia so that the infusion may be promptly stopped when the desired effect is achieved.

Caution: Potassium should not be used and may be dangerous for severe or complete heart block due to digoxin and not related to any tachycardia.

Other agents that have been approved for the treatment of digoxin intoxication include procainamide, lidocaine, and propranolol.

Pediatric Information: (See adult section for other recommendations for the treatment of arrhythmias produced by overdosages and for additional recommendations and cautions regarding the use of potassium.) Potassium preparations may be given orally in divided doses totaling 1-1.5 milliequivalents/kilogram (1 gram K contains 13.4 milliequivalents). When correction of the arrhythmia is urgent, approximately 0.5 milliequivalents/kilogram of potassium per hour may be given, with careful electrocardiographic monitoring, as a solution of 20 milliequivalents or less for 500 milliliters in 5 percent dextrose in water. The total dose should generally not exceed 2 milliequivalents of potassium/kilogram.

DOSAGE AND ADMINISTRATION: Oral digoxin is administered slowly or rapidly as required until the desired therapeutic effect is obtained without symptoms of overdosage. The amount can be predicted approximately from the lean body mass of the patient with allowances made for excretion during the time taken to induce digitalization.

Subsequent maintenance dosage is also determined tentatively by the amount necessary to sustain the desired therapeutic effect.

Recommended dosages are practical average figures that may require considerable modification as dictated by individual sensitivity or associated conditions. Diminished renal function is the most important factor requiring modification of recommended or average doses. (See WARNINGS and PRECAUTIONS sections.)

The average amount of digoxin that patients must accumulate to be digitalized with digoxin tablets is 1.0-1.5 milligrams. Digitalization may be accomplished by any of several approaches that vary in dosage and frequency of administration, but reach the same endpoint in terms of total amount accumulated.

In previously undigitalized patients, a single loading dose of 0.5-0.75 milligram orally usually produces a detectable effect in 1-2 hours that becomes maximal in 6-8 hours. Additional doses of 0.25-0.5 milligram may be given cautiously at 6-8 hour intervals to full digitalization.

In previously undigitalized patients, institution of daily maintenance therapy (0.125-0.5 milligram; see next paragraph) without a loading dose results in development of steady-state plateau concentrations in about 7 days in patients with normal renal function.

The average daily oral maintenance dose is 0.125-0.5 milligram, usually 0.25 milligram. In the elderly patient, 0.125-0.25 milligram should be considered the average maintenance dose.

In patients with renal impairment, digoxin excretion is impaired and serum half-life is prolonged. Digitalizing and maintenance doses are lower than those recommended for patients with normal renal functions. Signs of digoxin toxicity develop sooner in patients with renal impairment, and it takes longer for toxic signs and symptoms to disappear. Because of the prolonged half-life, a longer period of time is required to achieve an initial or new steady-state plateau in patients with renal impairment than in patients with normal renal function.

It cannot be overemphasized that the values given are averages and substantial individual variation can be expected.

Children: Digitalization must be individualized. Generally, premature and immature infants are particularly sensitive, requiring reduced dosage that must be determined by careful titration.

Oral Dosage. Beyond the immediate newborn period, children require proportionally greater doses than adults on the basis of body weight or surface area. The recommended oral digitalizing dosages in children with normal renal function are:

Newborn infants (normal), up to 1 month, require 40-60 micrograms (mcg)/kilogram.
Infants, 1 month to 2 years, require approximately 60-80 micrograms (mcg)/kilogram.
Children, 2 years to 10 years, require 40-60 micrograms (mcg)/kilogram.
Children, over 10 years of age, require adult dosages in proportion to their body weight.
Maintenance therapy is 20-30 percent of the digitalizing dose administered each day.

Long term use of digoxin is indicated in almost all infants who have been digitalized for acute congestive heart failure unless the cause is transient. Many favor maintaining digoxin until at least 2 years of age in all infants with paroxysmal atrial tachycardia or in those who show either definite or latent failure.

Many children with severe inoperable congenital defects need digoxin throughout childhood and often for life.

The primary goal of this study was to assess the frequency of persistent regional wall motion abnormalities and myocardial perfusion defects detectable late after myocardial infarction with radionuclide ventriculography and thallium-201 imaging, respectively. The study was performed prospectively in 32 patients in whom infarct size was estimated enzymatically at the time of the acute episode and in 10 patients without infarction. Thallium-201 imaging and radionuclide ventriculography were performed with the patient at rest an average of 11 months after infarction (range 6 to 20 months) and analyzed independently by two observers who were unaware of results of other clinical and laboratory data. Perfusion defects were detected in 94 percent (30 of 32) by observer I and in 91 percent (29 of 32) by observer II. Wall motion abnormalities were detected in 78 percent (25 of 32) and 75 percent (24 of 32) by observers I and II, respectively, but in 10 of the patients with an infarct size less than 20 creatine kinase-gram-equivalents (CK-g-eq), wall motion abnormalities were found in only 50 and 40 percent, respectively, by these observers ($p < 0.04$). Electrocardiographic changes of infarction (Q waves) were present in only 56 percent (18 of 32) of patients. Sixty-eight percent of patients with an infarct size greater than 20 CK-g-eq had persistent Q waves but these were present in only 30 percent with an infarct size less than 20 CK-g-eq ($p < 0.04$). The sites of perfusion defects and of wall motion abnormalities corresponded closely and were concordant with electrocardiographic localization. Thus, thallium-201 imaging and radionuclide ventriculography are sensitive noninvasive techniques for identifying prior myocardial infarction, and are particularly helpful in patients with conduction abnormalities or equivocal electrocardiographic findings.

The diagnosis or exclusion of remote myocardial infarction is a common and difficult problem in clinical medicine. If infarction is not documented at the time of the acute event, subsequent diagnosis frequently depends on recognition of electrocardiographic Q waves or demonstration of coronary arterial lesions and associated regional wall motion abnormalities at cardiac catheterization. A sensitive noninvasive index of prior myocardial infarction would be of considerable value in determining prognosis and facilitating management of patients, particularly those with congestive heart failure of occult origin, underlying conduction disturbances or a questionable clinical history of remote infarction.

Nuclear medicine techniques, including thallium-201 and technetium-99m pyrophosphate imaging[1–6] and, more recently, gated blood pool scintigraphy,[7–10] are assuming an increasing role in the diagnosis and assessment of acute myocardial infarction. However, the utility of these techniques in detecting remote myocardial infarction has not been thoroughly characterized in patients with infarction defined prospectively and in whom the extent of damage was quantified at the time of the acute episode. Accordingly, this prospective study was undertaken in patients with infarction documented and quantified initially by enzymatic estimation. We assessed the frequency of persistent regional wall motion abnormalities detectable with radionuclide ventriculography and of focal myocardial perfusion defects detectable with thallium-201 imaging 5 to 20 months after the acute episode.

Methods

Study Patients

The study group comprised 32 patients admitted with an initial myocardial infarction documented by a typical clinical history, acute electrocardiographic changes and elevation of plasma MB creatine kinase activity[11]; on the basis of electrocardiogram and history, all were found during follow-up study to have sustained no additional infarction. In addition, 9 of these patients had undergone technetium-99m pyrophosphate scintigraphy at the time of their admission for acute myocardial infarction. In all patients infarct size was estimated enzymatically from analysis of serial changes of plasma creatine kinase activity.[12] The details of the method[12] and its limitations[13,14] can be found in several recent reviews. All of the patients in this study were admitted within 6 hours of symptoms and a complete plasma creatine kinase activity curve was obtained. As noted in the Results, the range of infarct size was wide and virtually identical to the distribution of infarct size among all patients with initial infarction admitted during the interval in which this study was conducted (data not shown). The patients were evaluated 6 to 20 months after infarction and an electrocardiogram, a thallium scintigram and a radionuclide ventriculogram were obtained. Because we sought to detect residual myocardial scar rather than myocardial ischemia, these studies were performed at rest.

Control patients: To evaluate the problem of false positive test results, we studied 10 additional patients who had neither clinical nor electrocardiographic evidence of myocardial infarction and who had undergone cardiac catheterization because of recurrent transitory chest pain. The scintigraphic studies in this group were performed 24 to 48 hours after cardiac catheterization. Informed consent was obtained from all patients.

Diagnosis and localization of infarction: The site of infarction and its designation as either transmural or subendocardial were determined from electrocardiographic findings at the time of the initial hospitalization. Transmural myocardial infarction was defined by either development of new Q waves or marked loss of R waves in comparison with previous tracings. The electrocardiogram taken at the time of the study was considered diagnostic of prior myocardial infarction only if it contained significant Q waves, defined as (1) greater than 40 ms in duration, or (2) 20 to 40 ms in duration and more than 25 percent of the R wave in amplitude. Infarction was classified as inferior if these changes were noted in at least two of the inferior leads (II, III and aVF) and as anterior if they were present in one or more of the leads from V_2 through V_6. Poor R wave progression in the precordial leads without abnormal Q waves was not considered diagnostic of prior anterior myocardial infarction. Subendocardial myocardial infarction was defined as transient S-T and T wave changes at the time of initial hospitalization without subsequent development of Q waves in patients with enzymatically documented acute myocardial infarction.

Radionuclide Studies

Thallium imaging: Myocardial imaging at rest was performed after intravenous administration of 1.0 to 1.6 millicuries (mCi) of thallium-201 thallous chloride. The images were obtained with a standard field (25.4 cm diameter, 0.64 cm thick NaI crystal) scintillation camera (Searle LEM) fitted with a low energy, medium resolution, parallel hole collimator and interfaced to a dedicated minicomputer system (Ohio Nuclear VIP 450). Images were obtained in the anterior, 35° and 60° left anterior oblique and left lateral projections; each image consisted of 250,000 counts. Images were interpreted independently by two experienced observers who were unaware of both the clinical diagnosis and the results of gated blood pool studies. Images were viewed directly on the computer video-display with varying degrees of operator-controlled contrast enhancement. For analysis, the left ventricular myocardium was divided into five anatomic segments (anterior, septal, lateral, inferior and posterior walls) and the location of each defect was recorded.

Radionuclide angiography: Gated blood pool imaging was performed after labeling of the patients' red cells in vivo with technetium-99m.[15] This was accomplished by an intravenous injection of stannous pyrophosphate (7.7 mg) followed 15 to 30 minutes later by the injection of 20 to 25 mCi of technetium-99m. The images were collected with the same scintillation camera and computer system used for thallium scintigraphy. Each study consisted of multiple views including anterior, 30° to 45° left anterior oblique with 15° caudad angulation, and 70° left anterior oblique projections. Multigated acquisition of scintigraphic data was achieved according to the general technique described by Burow et al.[16]; the commercially available system used in this study divided the R-R interval into 32 equal time periods (frames). Each image frame consisted of approximately 250,000 counts.

Left ventricular ejection fraction was determined with a modification of the method of Burow et al.[16] with the use of a semiautomatic computer algorithm supplied by the manufacturer. Briefly, the operator first defined a tissue background region adjacent to the left ventricle after which the computer corrected each of the 32 frames for background activity. Then the operator defined an approximate region of interest surrounding the left ventricle on the end-diastolic frame and for each quadrant of this region selected the activity threshold that best corresponded to the left ventricular edge on this frame. The computer then applied an edge detection algorithm to define a left ventricular region of interest on each image frame and plotted activity in these variable regions versus frame number (time during the cardiac cycle). Ejection fraction was calculated as stroke activity (end-diastolic minus end-systolic activity in the left ventricle) divided by end-diastolic activity. The reliability of this method for determination of ejection fraction has been validated in our laboratory by comparison of the measurements obtained in 31 patients with those estimated from contrast angiography ($r = 0.91$) (unpublished observations).

Regional wall motion was evaluated independently by two observers who did not know the clinical diagnosis or the results of other studies and who interpreted the cinematic images directly on the computer video display. The wall motion of each of the five anatomic segments of the left ventricular wall

was scored subjectively as normal or abnormal (hypokinetic, akinetic or dyskinetic), and the location of each defect recorded.

Statistical analysis: The results for continuous measurements are expressed as mean ± standard deviation. Comparisons of group results were performed by Student's *t* test or chi-square test with continuity correction and correlations were performed by linear regression analysis.

Results

Extent and site of infarction: The 32 patients with prior myocardial infarction included 22 men and 10 women with a mean age of 58 years (range 43 to 76). They were studied between 6 and 20 months (mean 11) after myocardial infarction. The 10 patients without infarction consisted of 8 men and 2 women with a mean age of 55 years (range of 43 to 64). These patients, who were selected on the basis of normal left ventricular function and regional wall motion at cardiac catheterization, had a mean angiographically determined ejection fraction of 0.65 ± 0.7 (range 0.55 to 0.77). Six of these patients had completely normal coronary arteries and four had at least 50 percent stenosis of the diameter of one or more major vessels. One patient had obstruction in the right coronary artery, one in the left anterior descending artery, one in the circumflex artery and one in the left main coronary artery.

Enzymatic estimates of infarct size ranged from 2.5 to 78 creatine kinase-gram-equivalents (CK-g-eq) (Fig. 1). These values ranged from 12 to 78 CK-g-eq among the 12 patients with anterior (including anterolateral) myocardial infarction, from 2.5 to 46 CK-g-eq among the 11 with inferior (including inferoposterior) infarction, and from 5 to 42 CK-g-eq among the 9 with subendocardial infarction. Overall, infarct size was 20 or less CK-g-eq in 10 patients, 21 to 40 CK-g-eq in another 10 and greater than 40 CK-g-eq in the remaining 12.

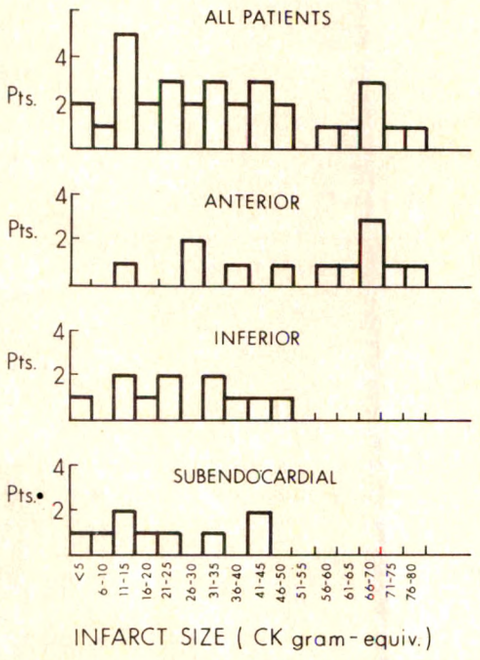

FIGURE 1. Distribution of infarctions according to size (CK-g-eq) and location among the 32 patients with myocardial infarction.

Thallium-201 imaging: Focal defects were seen in thallium-201 images from 29 to 30 of the 32 patients (91 and 94 percent) according to the two observers (Table I). Only 8 of the 10 patients (7 according to observer I) with an infarct size of less than 20 CK-g-eq exhibited a defect on thallium scans. The normal studies occurred in patients with a small inferior myocardial infarct of 2.5, 5 and 14.5 CK-g-eq, respectively (the two observers disagreed on the thallium findings in the patient with an infarct of 14.5 CK-g-eq). In the control patients, one observer interpreted all thallium-201 images as normal whereas the second observer described two (false positive) defects.

Radionuclide ventriculography: The two observers detected regional wall motion abnormalities with radionuclide ventriculography in 25 and 24 (78 and 75 percent) of the 32 patients, respectively (Table I). Among the 10 patients with an infarct size of less than 20 CK-g-eq, only 5 (4 according to observer II) had abnormal wall motion compared with 20 or 22 of those with a larger infarct ($p < 0.05$) (Table I). The patients with normal thallium-201 images also had a normal radionuclide ventriculogram. Normal studies were more frequent in patients with inferior or subendocardial infarction; all but one of the normal studies occurred in patients from these subgroups. In the control studies, one observer found no regional wall motion abnormalities, whereas the other observer interpreted one study as abnormal. Mean ejection fraction determined with radionuclide ventriculography in patients with myocardial infarction was 0.45 ± 0.14 compared with 0.59 ± 0.07 in control patients ($p < 0.05$). Late ejection fraction correlated weakly with initial infarct size estimated enzymatically during the acute phase (Fig. 2).

Follow-up electrocardiographic results: Q waves considered diagnostic of prior myocardial infarction were present on electrocardiograms obtained at the time

TABLE I

Results of Electrocardiographic and Radionuclide Studies in 32 Patients

	Cases (n)	Abnormal Thallium Image	Abnormal Wall Motion	Abnormal Electrocardiogram
All Patients				
Observer I	32	30 (94%)	25 (78%)	18 (56%)
Observer II	32	29 (91%)	24 (75%)	
Patients with infarct size >20 CK-g-eq				
Observer I	22	22 (100%)	20 (91%)	15 (68%)
Observer II	22	22 (100%)	20 (91%)	
Patients with infarct size <20 CK-g-eq

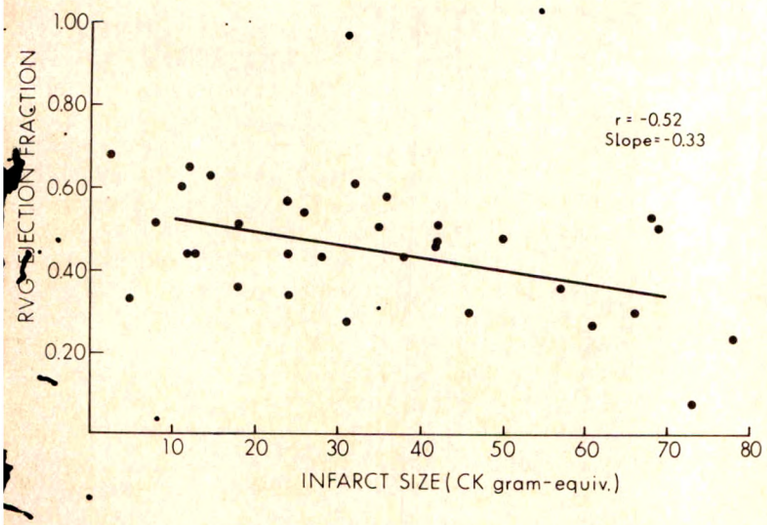

FIGURE 2. Relation between ejection fraction determined by radionuclide ventriculography (RVG) and infarct size estimated enzymatically.

of the follow-up radionuclide studies among 18 (56 percent) of the 32 patients (Table I). Thus, electrocardiography is much less sensitive for detection of remote myocardial infarction than either thallium-201 imaging ($p < 0.002$) or radionuclide ventriculography ($p < 0.03$). More patients (68 percent) with an enzymatically estimated infarct size greater than 20 CK-g-eq had persistent Q waves at the time of follow-up study than patients with an infarct size less than 20 CK-g-eq (30 percent) ($p < 0.04$). There was no significant difference in mean infarct size in the patients with loss of R wave amplitude or with transient Q waves compared with those with subendocardial infarction defined electrocardiographically at the time of the initial episode. Among the five patients with transmural myocardial infarction at the time of the initial episode who did not have Q waves at follow-up study, two had had Q waves at the time of their myocardial infarction that subsequently resolved. The other three patients did not have Q waves initially but did have serial decreases in R wave voltage.

Myocardial infarct scintigraphy: Technetium-99m pyrophosphate scintigrams were abnormal in 17 (89 percent) of the 19 patients who had undergone myocardial infarct scintigraphy during their admission for acute myocardial infarction. The two normal scintigrams were obtained from patients studied 4 and 6 days, respectively, after an initial subendocardial myocardial infarction. On the basis of separation of patients into two groups, those with anterior, anteroseptal or anterolateral infarction and those with inferior, inferoposterior or inferolateral infarction, the site of infarction as determined from the initial electrocardiograms, initial technetium-99m pyrophosphate images, follow-up thallium images and follow-up radionuclide ventriculograms corresponded in all cases.

Discussion

Thallium-201 Imaging

Our results indicate that focal myocardial scars persist and are detectable with thallium-201 scintigraphy late after myocardial infarction among patients with a wide range of infarct size, type (transmural or subendocardial) and location (anterior or inferior). Thallium-201 imaging detects areas of relatively decreased myocardial perfusion[17] that do not necessarily reflect irreversible injury. However, defects on thallium-201 images at rest do correlate in size with the pathologic extent of myocardial infarction[2] and, because our patients were studied at rest and in the absence of chest pain or electrocardiographic evidence of recurrent ischemia, these defects most likely reflected completed infarction.[18–21] Although detection of prior myocardial infarction with thallium-201 scintigraphy may exhibit a threshold phenomenon, abnormal results were frequently obtained even in patients with a small infarct (less than 20 CK-g-eq). Thus, substantial myocardial infarction of major clinical importance, sufficient to elicit impaired left ventricular dysfunction or late congestive heart failure, should always be detectable, except perhaps in the very rare situation of uniform global myocardial damage. Because all of the patients were studied more than 6 months after myocardial infarction, at a time when scar formation would be virtually complete, the perfusion defects that were detected should persist indefinitely.

Comparison with previous studies: Wackers et al.[1] performed thallium-201 imaging in patients 24 to 48 hours after acute myocardial infarction and observed an overall frequency of abnormal scans of 90 percent (including those interpreted as "positive" or "questionable"). Their study did not include a control group. Most of the patients studied (71 percent) had transmural myocardial infarction, but even among patients considered least likely to show positive results—those with a small infarct (peak serum glutamic oxaloacetic transaminase less than 3.5 times the upper limit of normal) and those undergoing scanning more than 48 hours after infarction—79 percent had an abnormal scan.

Recently Niess et al.[22] reported an overall sensitivity of 75 percent for thallium-201 imaging in detecting prior myocardial infarction. However, their study was re-

trospective, elevation of MB creatine kinase was not required to document myocardial infarction, and estimates of infarct size were not available. Nevertheless, 95 percent of patients with electrocardiographic evidence of prior myocardial infarction exhibited defects on thallium-201 images.

Radionuclide Ventriculography

Abnormal radionuclide ventriculograms were less frequent in this study than were abnormal thallium-201 scans, especially among patients with an infarct size less than 20 CK-g-eq. Nonetheless, persistent regional wall motion abnormalities were identified late after myocardial infarction in approximately 75 percent of patients. The site of abnormality determined by this method corresponded to the site of defects in thallium-201 scans, as well as to the site of technetium-99m pyrophosphate uptake and electrocardiographic abnormalities present at the time of the index infarction.

Correlation of infarct size and location and left ventricular function: In the study of Niess et al.,[22] regional wall motion abnormalities were noted at cardiac catheterization in all patients studied who had electrocardiographic evidence of transmural myocardial infarction but in only 84 percent of the entire group catheterized. Although radionuclide ventriculography is a less sensitive modality than thallium scintigraphy for detecting prior myocardial infarction, especially for small and inferior infarctions, it provides additional information characterizing left ventricular function. The results of both first pass and multigated radionuclide ventriculograms correlate well with clinical status and prognosis,[7,23] with left ventricular function assessed echocardiographically[24] and with left ventricular ejection fraction determined with contrast ventriculography.[16,25] In our study the weak correlation between the initial estimate of infarct size and radionuclide ejection fraction, determined much later, is not surprising because the extent of occult underlying myocardial disease may lead to relatively extensive depression of ejection fraction, or a particularly favorable distribution of infarction may result in relative preservation of ejection fraction compared with that based on consideration of extent of infarction alone.[26] In this study, we did not assess right ventricular function, which is frequently abnormal in patients with inferior infarction. In some of these patients, only right ventricular function may be impaired, and it is thus possible that evaluation of right ventricular ejection fraction and regional wall motion might improve the sensitivity of radionuclide ventriculography for detection of prior inferior infarction.

Electrocardiography

The electrocardiogram is a relatively insensitive index of old myocardial infarction.[27,28] Subendocardial myocardial infarction often cannot be documented at all late after an episode, Q waves may resolve after a transmural event, Q waves on the inferior leads may be equivocal, or conduction disturbances may mask electrocardiographic criteria of infarction. Specificity is also a problem[28] because chronic obstructive pulmonary disease, ventricular hypertrophy or conduction disturbances may give rise to Q waves in the absence of infarction. The frequency of positive results with both thallium scintigraphy and radionuclide ventriculography in our study was significantly greater than that with the electrocardiogram in patients with prior myocardial infarction (Table I). Nevertheless, the site of myocardial infarction, when evident electrocardiographically, correlated with the location of perfusion defects as has been noted by other investigators.[2,6,22]

Implications

Both thallium-201 scintigrams and radionuclide ventriculograms are frequently positive among patients with prior myocardial infarction. The magnitude of interobserver variability in interpretation of both the thallium-201 images and the radionuclide ventriculograms in our study is similar to that reported by earlier investigators.[29,30] This degree of variability should not seriously hamper the utility of these techniques for detection of remote myocardial infarction. Scintigraphically detectable perfusion defects persist for at least 6 months and, presumably, indefinitely. The sites of thallium defects and of regional wall motion abnormalities correspond closely and are concordant with electrocardiographic and technetium-99m pyrophosphate sites of antecedent acute myocardial infarction. Radionuclide ventriculography provides additional information characterizing late left ventricular function. Thus, these nuclear medicine techniques should be helpful in identifying and localizing prior myocardial infarction, particularly among patients with intraventricular conduction abnormalities or equivocal electrocardiographic findings.

Abnormalities of left ventricular contraction in patients with mitral valve prolapse have suggested a myocardial factor in this disease. To determine systolic left ventricular function in mitral valve prolapse, technetium-99m gated equilibrium radionuclide cineangiography was performed in 47 patients with this diagnosis. In 39 patients without mitral regurgitation the average ejection fraction was normal at rest (average [± standard error of the mean] 57 ± 3 percent, normal 57 ± 1 percent, difference not significant) and exceeded the lower limits of normal in all but 1 patient, whose ejection fraction was 41 percent. However, ejection fraction during maximal exercise was lower for the group of patients with mitral prolapse without mitral regurgitation than for normal subjects (average 64 ± 2 percent, normal 71 ± 2 percent, $p<0.005$). In eight patients with mitral prolapse and mitral regurgitation, the average ejection fraction was normal at rest but was diminished with exercise in comparison with both normal subjects and patients with mitral valve prolapse without mitral regurgitation. Chest pain, arrhythmia and the pattern or extent of mitral valve prolapse on echocardiography were not independently associated with impaired left ventricular functional reserve. We conclude that, although many patients with mitral valve prolapse have normal left ventricular function, there is a subgroup without mitral regurgitation in whom diminished left ventricular functional reserve is suggestive of a cardiomyopathic process.

The presence of left ventricular contraction abnormalities,[1,2] chest pain and ventricular arrhythmia in patients with mitral valve prolapse suggested a myocardial component in this condition. In addition, symptoms and electrocardiographic abnormalities associated with mitral valve prolapse may not be easily distinguished from those of coronary artery disease. Because it has recently become evident that mitral valve prolapse is a relatively common disorder, occurring in 5 to 10 percent of our population,[3–5] it is of practical importance to determine the functional derangements associated with this condition and to define a reliable noninvasive means of excluding hemodynamically important coronary arterial obstruction in those patients with mitral valve prolapse and symptoms suggestive of ischemia.

In this study, we employed radionuclide cineangiography in patients with mitral valve prolapse to assess systolic left ventricular performance at rest and during exercise, independent of coexisting coronary artery disease. The results of this functional assessment were correlated with the clinical, echocardiographic and electrocardiographic findings in patients with this condition.

Methods

Study patients: Patients with mitral valve prolapse seen at the National Heart, Lung, and Blood Institute between May 1978 and February 1979 were studied. The group consisted of 33 women and 14 men, aged 15 to 65 years (mean 39). Of these 47 patients, 39 (10 men and 29 women with a mean age of 39 years) did not have clinically important mitral regurgitation, as determined from the physical examination, absence of left atrial or left ventricular enlargement on

echocardiography and, in 10 patients, the findings on left ventricular contrast angiography. Eight patients did have moderate or severe mitral regurgitation confirmed angiographically. Coronary angiography was performed in 10 patients.

The presence of mitral valve prolapse was determined by the finding of a midsystolic click on auscultation, with or without the presence of a late systolic murmur. The criteria for mitral valve prolapse on echocardiography were applied as described elsewhere.[6] A patient was judged to have mitral valve prolapse if either echocardiographic or auscultatory criteria were present. Of 39 patients without clinically important mitral regurgitation, 30 had a mid systolic click at the time of study. Of nine patients without a click, seven had a late systolic apical murmur. The two patients without auscultatory evidence of mitral prolapse each had a markedly positive mitral valve echogram, with late systolic posterior displacement of the mitral valve from the C-D line exceeding 5 mm. In all patients administration of cardiac medications was discontinued at least 72 hours before study.

Echocardiographic techniques: Echocardiograms were performed with a 2.25 megahertz, 1.25 cm diameter unfocused transducer connected to a commercially available ultrasonograph and strip chart recorder. Each patient was studied in the basal state in a supine position. Care was taken to record both mitral valve leaflets with the transducer held perpendicular to the chest wall, usually at the fourth or fifth left intercostal space.[7] To prevent a false pattern of mitral valve prolapse, caudal angulation of the transducer was avoided.[8] End-diastolic left ventricular dimensions were measured as the maximal distance between the left side of the interventricular septum and endocardium of the posterior free wall[9] with the ultrasonic beam passing through the left ventricle at or slightly caudal to the tips of the mitral leaflets.

Electrocardiograms: Standard 12 lead electrocardiograms were obtained in each patient. Ambulatory 24 hour electrocardiographic records on magnetic tape were obtained in 37 patients during normal activity. The playback was displayed in real time on a large screen oscilloscope (Clinical Data Inc., Boston, Massachusetts) for visual identification of ectopic beats and other arrhythmias, which were subsequently tabulated by computer. Ventricular arrhythmia was graded according to a system similar to that discribed by Lown et al.[10] The following categories were used:

Grade 0: no ventricular premature depolarizations in 24 hours.

Grade 1: occasional ventricular premature depolarizations; no more than 30 in any hour of monitoring.

Grade 2: more than 30 ventricular premature depolarizations in any hour of monitoring or more than 1 such depolarization in 2 minutes of exercise testing.

Grade 3: multiform ventricular premature depolarizations.

Grade 4a: ventricular couplets (two consecutive ventricular premature depolarizations).

Grade 4b: ventricular tachycardia, that is three or more consecutive ventricular premature depolarizations in succession.

Exercise testing: Upright bicycle ergometry was performed using a modified CM_5 system, including a V_5 lead for detection of abnormalities with an anterior vector and a sacral lead for detection of abnormalities with an inferior vector. Exercise was continued until the development of chest pain or limiting fatigue. The exercise electrocardiogram was assessed for the presence of arrhythmias and repolarization abnormality; S-T segment depression with a flat or negative slope of 0.1 mV for 80 ms or more in either monitored lead was considered a positive response.

Radionuclide cineangiography: Radionuclide cineangiography was performed with the subjects in a supine position at rest and during maximal symptom-limited supine bicycle exercise.[11] In vivo labeling of red blood cells with 10 to 15 millicuries of technetium-99m was effected by injecting the isotope 30 minutes after the intravenous administration of stannous pyrophosphate. This dose of technetium coupled with a high sensitivity collimator results in 20,000 events/s in a 15 by 15 cm field of view surrounding the heart. Background radiation was determined by creating a crescent of pixels located 1 pixel width outside the lateral border of the region of interest. After equilibration of the tracer in the blood pool, a Anger camera was oriented in the modified left anterior oblique position to isolate the left ventricle in the field of view.[12] Angulation of the camera 15° toward the feet, that the camera is approximately perpendicular to the long axis of the left ventricle, helps to exclude the left atrium from the left ventricular area of interest. Imaging was performed with the use of a computer-based procedure gated to the electrocardiogram, as described elsewhere.[13] To further exclude contribution of atrial activity to the left ventricle, only the difference image is used to draw the left ventricular area of interest at the level of the valve plane. Hence, if there were an area of overlap of the left ventricle and left atrium, exclusion of counts from the overlying left atrium, as well as from a small portion of the base of the left ventricle, would occur in systole and diastole. This technique, while excluding left atrial contamination, causes negligible error in the determination of global left ventricular ejection fraction. Left ventricular ejection fraction could then be determined by computer-assisted analysis of left ventricle time-activity curves.[13] Excellent correspondence ($r \pm 0.92$, $p < 0.001$) of radionuclide ejection fractions with those obtained with contrast angiography has been previously established.[14]

After images were obtained at rest, supine bicycle exercise was begun with 25 watt increments in the exercise load at 3 minute intervals. Exercise was continued until limitation by severe fatigue, chest pain or severe dyspnea. Imaging was begun when the patient indicated moderate fatigue, and continued until the symptom-limited end point. In all subjects, heart rate and blood pressure (measured using arm cuff sphygmomanometry) were recorded at 1 to 2 minute intervals during exercise. After completion of imaging the portion of the image sequence corresponding to maximal exercise was selected for analysis.[13] Each patient underwent continuous imaging throughout most of the exercise period, beginning with mild to moderate exercise, and continuing through the termination of exercise. Beat length windowing (list mode data acquisition) was employed to permit selection of that portion of the imaging sequence corresponding to maximal exercise, always including the last 1.5 to 2 minutes of exercise. Regional wall motion was determined visually by two independent observers directly from the cine display. Whereas assessment of the anteroseptal and anterolateral ventricular walls was made directly from the latter, functional evaluation of regions of myocardium not contributing to the edges of the cardiac silhouette in the modified left anterior oblique position was performed from difference images created by subtracting the end-systolic from the end-diastolic image.

Ejection fractions obtained at rest and during exercise were compared with those previously determined in 30 normal subjects.[13,14] The normal subjects ranged in age from 19 to 63 years and had no clinical, echocardiographic or electrocardiographic evidence of cardiovascular disease. Nine of these normal subjects were women and 21 were men.

Statistical comparisons were made using Student's *t* test. Data were expressed as the average ± standard error of the mean.

Results

Mitral Valve Prolapse Without Mitral Regurgitation

Radionuclide cineangiography: Ejection fraction at rest in 39 patients without mitral regurgitation (Fig. 1) averaged 57 ± 3 percent compared with 57 ± 1 percent for normal subjects (difference not significant [NS]) and equaled or exceeded the lower limits of normal (45 percent) in all but 1 patient. In this patient the ejection fraction at rest was 41 percent. In contrast, ejection fraction during maximal exercise was 64 ± 2 percent, compared with 71 ± 2 percent for normal subjects ($p < 0.005$) and was below the lower limits of normal, that is, 58 percent during maximal exercise,[14] in nine (23 percent) patients. Of these nine patients, five who achieved a heart rate of 113 to 178 beats/min (mean 144) during maximal exercise had an ejection fraction during maximal exercise that was marginally depressed (55 to 57 percent). Values as low as 54 percent have been recorded during submaximal exercise (heart rate 105 to 120 beats/min) in normal subjects.[13] Because the number of normal subjects studied was relatively small, the significance of a borderline low ejection fraction during maximal exercise in these five patients with mitral valve prolapse is uncertain. However, in four patients, who also achieved an appropriate response of heart rate to maximal exercise, the ejection fraction during maximal exercise was substantially decreased (less than 54 percent) to levels below those noted in any normal subject even during mild exercise. Hence, these four persons with mitral prolapse probably did manifest diminished left ventricular functional reserve.

Ejection fraction was distinctly abnormal in two patients, one of whom showed a marked decline in ejection fraction from an initially normal value of 69 percent at rest to a clearly abnormal value of 47 percent during exercise. In the other patient, an initially low ejection fraction at rest of 41 percent showed no increase with exercise. All normal subjects showed an increase in ejection fraction with exercise.

Role of heart rate and blood pressure: Although marked differences in heart rate may influence ejection fraction,[14] the heart rates (average 75 ± 2 beats/min at rest, 136 ± 3 beats/min during exercise) of the patients with mitral valve prolapse did not differ importantly from average heart rates at rest (66 ± 2 beats/min) and during exercise (143 ± 3 beats/min) of the normal subjects. The average systolic blood pressure at rest (122 ± 4 mm Hg) was higher than that in normal subjects (114 ± 2 mm Hg, $p < 0.01$). With exercise, systolic blood pressure in patients with mitral valve prolapse (171 ± 5 mm Hg) was somewhat lower than that of the normal subjects (189 ± 4 mm Hg). However, comparison of the patients with mitral prolapse (predominantly female) with normal women shows no significant differences in heart rate at rest (average 71 ± 3 beats/min) or during exercise (average 149 ± 4 beats/min), and systolic blood pressure during exercise (178 ± 5 mm Hg). In the patient whose low ejection fraction at rest of 41 percent failed to increase with exercise, heart rate increased from 71 beats/min at rest to 120 beats/min with exercise, accompanied by an increase in systolic blood pressure from 140 mm Hg at rest to 190 mm Hg with exercise. Another patient with an ejection fraction of 54 percent at rest and only 55 percent with exercise manifested a heart rate of 76 beats/min at rest and 135 beats/min with exercise. Systolic blood pressure increased from 145 to 220 mm Hg.

Role of coronary artery disease: In the two patients with an abnormal response of ejection fraction to exercise, coronary angiography failed to disclose coronary arterial abnormality. Regional wall motion abnormality at rest or with exercise was not observed in any patient with mitral valve prolapse.

To exclude the possible influence of occult coronary arterial stenosis, a separate assessment of left ventricular function was performed in 20 of the 39 patients without mitral regurgitation. This subgroup contained 10 patients with normal coronary arteriograms and 10 patients who did not have coronary arteriography but were unlikely to have coronary artery disease because they were women under 40 years of age (Fig. 2). Even in this subgroup, ejection fraction with exercise was significantly lower in patients with mitral valve prolapse than in normal subjects. Furthermore, three patients with prolapse and a normal coronary arteriogram, including one patient with an abnormal ejection fraction at rest, had a subnormal ejection fraction during exercise.

Clinical features: Chest pain was noted in 21 (54 percent) and palpitations were reported in 20 (51 percent) of the 39 patients with mitral valve prolapse and no mitral regurgitation. However, among the 31 patients who underwent 24 hour electrocardiographic monitor-

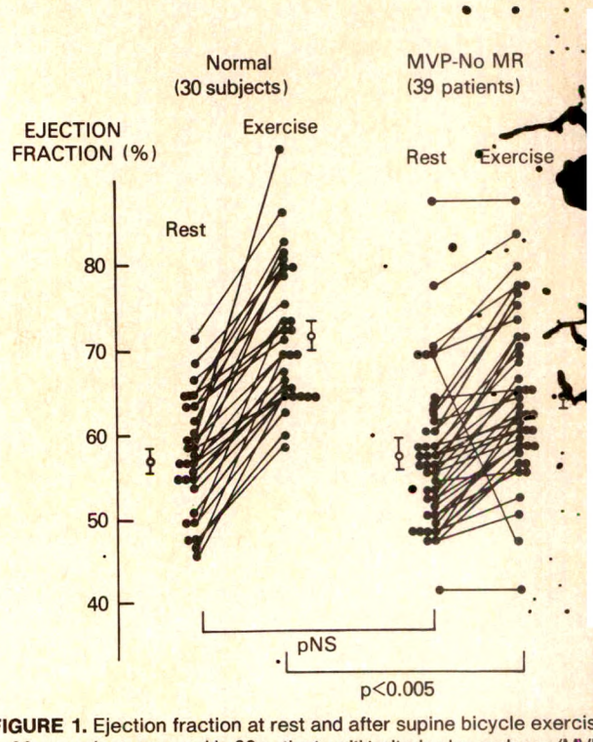

FIGURE 1. Ejection fraction at rest and after supine bicycle exercise in 30 normal persons and in 39 patients with mitral valve prolapse (MVP) but no mitral regurgitation (MR). See text for discussion. NS = not significant; p = probability.

ing, there was no difference in ejection fraction at rest or during exercise in patients with and without chest pain. Nine of the 31 patients had Lown grade 2 through 4b ventricular arrhythmia and 22 had grade 0 or grade 1 ventricular arrhythmia. Although the former group had a slightly lower ejection fraction with exercise (Fig. 3) than the latter, this difference was not statistically significant (61 ± 5 versus 64 ± 2 percent). Three patients had 0.1 mV S-T segment depression during maximal upright bicycle exercise. One of these three patients evidenced decreased left ventricular functional reserve, with ejection fraction decreasing from 69 percent at rest to 47 percent during exercise.

Echocardiography: Echocardiograms were sufficient for evaluation in 36 of 39 patients. Late systolic prolapse was apparent in 21 patients (58 percent) and holosystolic prolapse in 10 patients (28 percent). Five subjects had echocardiograms that were not diagnostic of mitral prolapse. The diagnosis in these patients was determined by the auscultatory finding of a mid systolic click with or without a late systolic murmur. Posterior displacement of the C-D line in the mitral valve echogram exceeded 5 mm in 12 patients (average 7 mm) and was 4 mm or less in 24 patients (average 3 mm, $p < 0.001$). There was no significant difference in ejection fraction between these two groups (Fig. 4) at rest or with exercise (60 ± 3 percent in patients with 5 mm or greater C-D displacement, 66 ± 2 percent in patients with 4 mm or less). There was also no relation between left ventricular function and the pattern of mitral valve prolapse on echocardiogram. Left atrial dimension was normal in all patients, including those with left ventricular dysfunction.

Mitral Prolapse and Mitral Regurgitation

The eight patients with mitral valve prolapse and moderate to severe mitral regurgitation had an ejection fraction at rest of 56 ± 3 percent and did not differ significantly from normal subjects or from patients with mitral valve prolapse without mitral regurgitation (Fig. 5). However, left ventricular functional reserve for this group was diminished compared with that in patients without mitral regurgitation, as evidenced by a subnormal average ejection fraction during exercise of 53 ± 4 percent compared with 64 ± 2 percent in patients without mitral regurgitation ($p < 0.01$). Subnormal ejection fraction during maximal exercise has also been noted in patients with mitral regurgitation from causes other than mitral prolapse.[15] Four of the five patients with mitral prolapse and mitral regurgitation whose ejection fraction decreased during exercise (Fig. 5) had left ventricular end-diastolic dimensions on echocardiography greater than 66 mm. However, the small number of patients does not permit a statistically valid evaluation of the relation between left ventricular diastolic dimensions and left ventricular function.

Discussion

Although myxomatous degeneration of the mitral valve is the principal abnormality in mitral valve prolapse, the presence of "ischemic" electrodiographic changes,[16,17] chest pain,[18,19] arrhythmias[20] and the occasional occurrence of sudden death not due to severe mitral regurgitation and congestive heart failure[18,21,22] suggest the coexistence of a primary myocardial abnormality. Hemodynamic studies demonstrating that

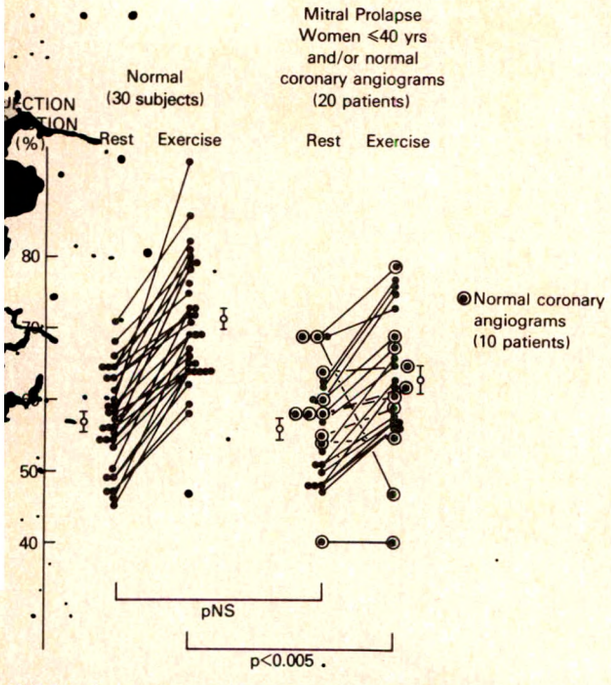

FIGURE 2. Comparison of ejection fraction at rest and with exercise in 30 normal subjects and 20 patients with mitral valve prolapse and normal coronary arteriograms or women less than 40 years of age. The two patients with clearly abnormal left ventricular function both had normal coronary arteriograms.

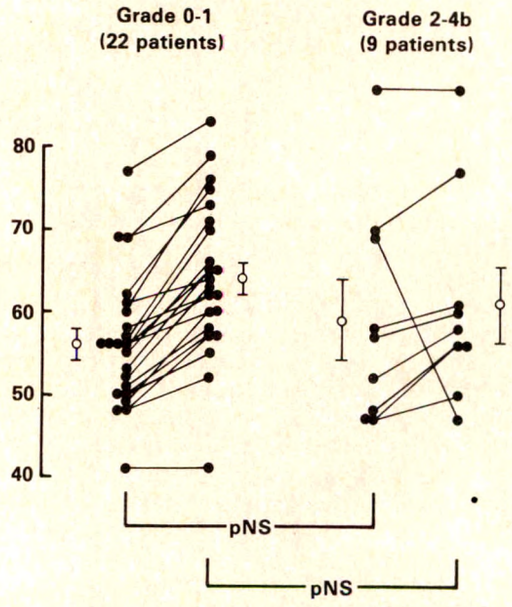

FIGURE 3. Systolic left ventricular function at rest and with exercise in patients with no or minimal (grade 1) ventricular arrhythmia compared with those patients with more severe grades (2–4b) of arrhythmia. No significant differences between groups are noted.

some patients have elevated left ventricular end-diastolic pressure, decreased cardiac index at rest, failure of the cardiac index to increase appropriately with exercise, and abnormalities of left ventricular wall motion[1,2,23] also suggest a myocardial component, as does the finding of myocardial histologic abnormalities on transvenous endomyocardial biopsy.[24]

Our findings demonstrate that abnormalities in left ventricular function occur in patients with mitral valve prolapse and mitral regurgitation. However, decreased left ventricular functional reserve has also been noted in patients with mitral regurgitation from causes other than mitral prolapse,[15] probably reflecting the effects of chronic volume overload. Hence, the interpretation of such a finding in patients with mitral prolapse and regurgitation is ambiguous. More convincingly, ejection fraction during exercise was below the limits of normal, or declined from values at rest, in several patients with mitral prolapse who did *not* manifest clinically apparent mitral regurgitation. Moreover, the mean ejection fraction during exercise for this group, or for the patients with mitral valve prolapse without mitral regurgitation *and* with no or little likelihood of coronary disease, was lower than that of normal subjects.

Mechanism of myocardial dysfunction in mitral prolapse: Although these abnormalities suggest that a primary aberration of myocardial function exists in some patients with mitral valve prolapse, alternative explanations are possible. For example, in our patients who had no evidence of mitral regurgitation at rest, mitral regurgitation could have developed during exercise and could conceivably have been responsible for the abnormal left ventricular function observed during exercise. However, although patients with chronic mitral regurgitation may evidence abnormal left ventricular reserve as indicated by a decrease in ejection fraction during exercise, acute mitral insufficiency developing during exercise in those patients with mitral valve prolapse who do not have mitral regurgitation at rest would be expected to provide a low impedance runoff for the left ventricle. Hence, an increase in ejection fraction during exercise, rather than the observed decrease, would be likely.

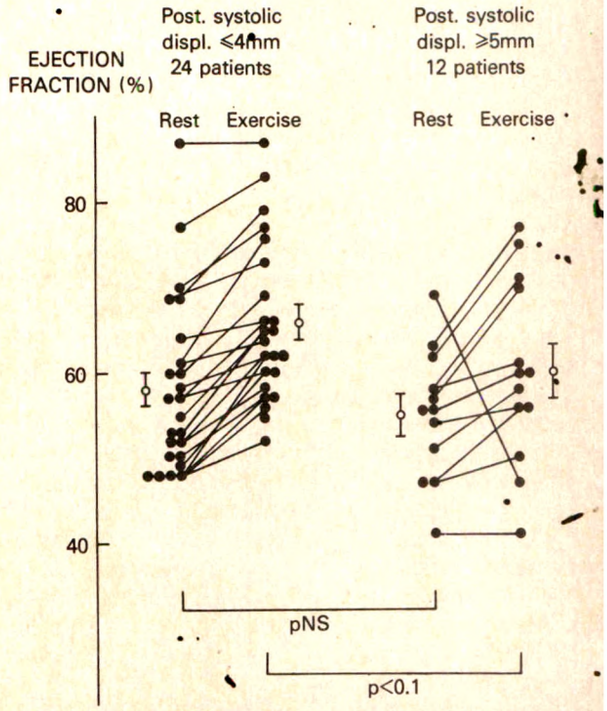

FIGURE 4. Left ventricular systolic function at rest and with exercise categorized according to extent of mitral prolapse estimated from M mode echocardiogram. Differences noted do not achieve statistical significance. displ. = displacement; Post. = posterior.

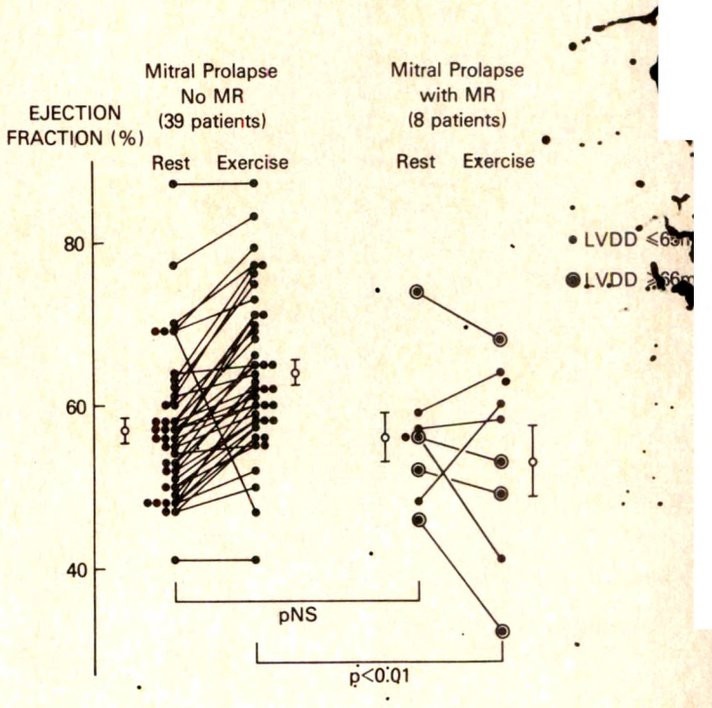

FIGURE 5. Comparison of left ventricular ejection fraction in those patients with mitral valve prolapse with (n = 39) and without (n = 8) concomitant mitral regurgitation (MR). Although ejection fraction in the two groups is the same at rest, it is significantly lower with exercise in patients with than in those without mitral regurgitation. LVDD = left ventricular end-diastolic diameter in echocardiogram.

In criticism of other results suggesting a "myocardial" theory of mitral valve prolapse, Jeresaty[25] noted the confusing heterogeneity of left ventricular wall motion abnormalities that have been described, and thought that some of these abnormalities might have been factitious. Even if regional wall motion abnormalities did exist, he suggested that fibrosis of papillary muscles and regions of adjacent myocardium, consequent to traction from mitral leaflet "sail forces," might explain hypokinesia or akinesia. The disappearance of left ventricular contraction abnormalities in patients with mitral valve prolapse after mitral valve replacement[26] supports this "valvular" theory of mitral prolapse, at least for the abnormalities seen in some patients. However, these considerations do not account for the decrease in global left ventricular functional reserve and absence of regional wall motion abnormality noted in our patients. Moreover, if abnormalities in left ventricular function and the occurrence of chest pain and arrhythmias were secondary to the effects of mitral valve prolapse on the papillary muscles and their myocardial attachments, one might expect the presence of left ventricular dysfunction to be related to the severity of prolapse. However, neither the extent nor the pattern of mitral prolapse assessed with echocardiography correlated with the presence of chest pain, the extent of rhythm abnormality or the development of abnormal left ventricular function during exercise.

Myocardial perfusion abnormalities represent another potential cause of abnormal left ventricular function in patients with mitral valve prolapse. Preliminary communications[27,28] have suggested the presence of myocardial perfusion defects on thallium scan at rest as well as during exercise in patients with mitral valve prolapse; however, Klein et al.[29] found normal myocardial perfusion during exercise stress in all 22 patients studied who had normal coronary arteriograms, despite the presence of chest pain or positive echocardiographic exercise stress tests in many. The latter results have been independently confirmed by others.[30,31]

Clinical implications: Of practical importance to the management of patients who have a disease with symptoms simulating coronary artery disease is the development of a noninvasive means of distinguishing those patients with mitral prolapse and coincidential coronary artery disease from those patients with mitral valve prolapse and normal coronary arteries. Only a small subgroup of our patients with mitral valve prolapse had an abnormal ejection fraction response to exercise and no patient in the present series evidenced regional left ventricular dysfunction, abnormalities usually found in patients with coronary artery disease.[11] It may therefore be inferred that the absence of these abnormalities on radionuclide cineangiography in a patient with mitral prolapse excludes with high probability the presence of coexisting significant coronary artery disease. The converse, however, is less certain. Abnormal global left ventricular function may be present in patients with mitral prolapse in the absence of coronary artery disease. Also, while none of our patients evidenced asynchronous left ventricular wall motion on radionuclide cineangiography, this finding by other investigators[1,2] using contrast left ventriculography suggests that the presence of regional contraction abnormalities may not unequivocally denote underlying coronary disease in patients with mitral valve prolapse.

Cardiac Function During Rest and Exercise in Patients With Mitral Valve Prolapse

Role of Radionuclear Angiocardiography

GLENN E. NEWMAN, MD
RAYMOND J. GIBBONS, MD
ROBERT H. JONES, MD, FACC

Durham, North Carolina

The clinical features of mitral valve prolapse syndrome and ischemic coronary disease overlap, making differentiation of the two conditions difficult. Furthermore, many patients have both conditions. This study assessed changes in ventricular function during rest and exercise in patients with mitral valve prolapse alone and in patients with prolapse and concomitant coronary artery disease. Twelve patients with angiographically documented mitral valve prolapse and normal coronary anatomy and 11 patients with normal coronary anatomy and no mitral valve prolapse had increased ejection fraction and demonstrated no wall motion abnormality during exercise. Changes in ventricular function during exercise in 11 additional patients with mitral valve prolapse demonstrated on echocardiography were similar to those in the group with mitral valve prolapse and normal coronary anatomy seen on angiography. In contrast, 6 of 11 patients with mitral valve prolapse and coronary arterial stenosis demonstrated on angiography had a decreased ejection fraction and exhibited wall motion abnormalities during exercise. These results suggest that mitral valve prolapse alone has no detrimental effect on ventricular function during rest and exercise and that exercise-induced abnormalities in ventricular function are related to the presence and severity of coronary artery disease and not to mitral valve prolapse.

Prolapse of the mitral valve is a common but usually innocuous disorder. The clinical features of this syndrome frequently mimic those of ischemic heart disease[1,2] and its diagnosis is further complicated by the relatively common coexistence of coronary artery disease.[3,4] In addition, mitral valve prolapse in patients with normal coronary arteries has been suggested as one potential cause of myocardial ischemia. Because of these considerations, patients with mitral valve prolapse commonly come to cardiac catheterization. Noninvasive diagnostic techniques have been developed that hold the potential for assessing both prolapse of the mitral valve and myocardial ischemia. Measurement of left ventricular function during rest and exercise with radionuclide angiocardiography appears to be a sensitive technique for recognition of coronary artery disease, and patients with myocardial ischemia typically exhibit a decrease in ejection fraction and new wall motion abnormalities during exercise.[5,6] Left ventricular function during rest and exercise has not been evaluated in patients with mitral valve prolapse. The purpose of this investigation was to assess whether prolapse of the mitral valve without concomitant coronary artery disease can cause cardiac functional alterations during exercise and whether patients with both mitral valve prolapse and coronary artery disease can be separated from patients with the former disorder alone.

Methods

Patients: Radionuclide angiocardiography during rest and exercise has been performed as a clinical study at Duke University Medical Center since April 1977. Since then, 455 patients underwent both cardiac catheterization for evaluation of chest pain and radionuclide angiocardiography during rest and exercise. In

the same period, 296 patients underwent echocardiography and radionuclide angiocardiography during rest and exercise but did not undergo cardiac catheterization. Retrospective analysis of these patients by retrieval of data from a computerized information system identified four homogeneous groups for this study.[7] Group I consisted of persons documented to have a totally normal cardiovascular system except for a history of chest pain. Group II comprised patients with normal coronary arteriograms and definite mitral valve prolapse documented during contrast left ventriculography. Group III consisted of patients with a 75 percent or greater reduction in the diameter of at least one major coronary artery on coronary angiography and definite mitral valve prolapse on left ventriculography. Group IV was defined as patients with definite mitral valve prolapse demonstrated on echocardiography; patients in this group did not undergo cardiac catherization.

Group I: The 11 normal patients (4 women, 7 men) in this group had a mean age (± standard error of the mean) of 48 ± 8 years (range 35 to 58). Five patients presented with nonanginal chest pain, five with atypical angina and one with a history of typical angina. No patient had a history of hypertension, myocardial infarction or prior positive exercise treadmill test. Nine patients had a normal electrocardiogram, and two had nonspecific ST-T wave changes. All 11 patients underwent complete cardiac catheterization and had normal hemodynamic measurements, completely normal coronary arteriogram without even minor irregularities, normal left ventricular function with a resting ejection fraction greater than 0.50 and no mitral valve prolapse. In addition, no patient was taking medication with known cardiac effects near the time of radionuclide angiocardiography.

Group II: This group consisted of 12 patients, 8 women and 4 men, with mitral valve prolapse but no coronary artery disease demonstrated at cardiac catheterization. Their mean age was 49 ± 10 years (range 35 to 62). Seven had been evaluated for chest pain atypical of angina, three for typical chest pain and one because of a previous positive exercise treadmill test. Of the 10 patients presenting with chest pain, 7 had previously been hospitalized one or more times for severe chest pain, but no myocardial infarction had been documented with serial electrocardiograms or cardiac enzyme assay. Eight of the 12 patients had either a systolic click or a midsystolic murmur. Four had nonspecific ST-T wave changes, and eight a normal electrocardiogram. Three of the eight patients who underwent treadmill testing had a positive exercise treadmill examination immediately before cardiac catheterization. Cardiac catheterization in this group documented definite mitral valve prolapse but normal hemodynamic findings and coronary arteries. Left ventriculography revealed a trace of mitral regurgitation in three patients and no mitral regurgitation in nine. The 12 patients appeared to have a normal cardiovascular system except for prolapse of the mitral valve documented angiographically.

Group III: This group consisted of 11 patients, 4 women and 7 men, with mitral valve prolapse associated with coronary artery disease. Their mean age was 48 ± 5 years (range 38 to 54). All 11 patients had chest pain that was considered typical of angina in 8 and atypical of angina in 3. Six patients had previously been hospitalized one or more times for severe pain, but myocardial infarction was not documented. Four patients had either a systolic click or a mid systolic murmur. Eight had a normal electrocardiogram, and three had nonspecific ST-T wave changes. Of nine patients undergoing exercise treadmill testing, five had positive results, three indeterminate results and one a negative result. Cardiac catheterization confirmed prolapse of one or both cusps of the mitral valve in all patients, and three had a trace of mitral regurgitation seen on left ventriculography. Coronary arteriograms demonstrated lesions obstructing at least 75 percent of the vessel diameter in all patients, and these lesions were present in one major coronary artery in three patients, two major coronary arteries in four and all three major coronary vessels in four. These patients can be characterized as having documented coexistence of mitral valve prolapse and coronary artery disease.

Group IV: The 11 patients in Group IV, 7 women and 4 men, had mitral valve prolapse on echocardiography but no other demonstrable cardiac disease. These patients did not undergo cardiac catheterization so that the presence of coronary artery disease in this group could not be definitely excluded, but they did undergo radionuclide angiography. Their mean age was 39 ± 15 years (range 21 to 63). The five patients had presented with a history of atypical chest pain, four with palpitations and two with a previous positive exercise treadmill tests. No patient had had a prior myocardial infarction documented. Therefore, this group comprised patients with an echocardiographic diagnosis of mitral valve prolapse in whom the diagnosis of coronary artery disease did not appear likely but was not excluded by coronary arteriography.

Cardiac catheterization: All patients in Groups I, II and III underwent right and left heart catheterization that included right and left heart pressure measurements, collection of oxygen data, biplane left ventriculography and selective coronary arteriography. Mitral valve prolapse was diagnosed when one or both of the mitral leaflets was seen to move into the left atrium during systole in both the right anterior and left anterior oblique views.[8] The magnitude of mitral valve insufficiency was subjectively classified on a scale of 0 to 4 as determined by the rate of contrast clearance from the left atrium. Patients with 1+ or less mitral regurgitation were considered to have a trace amount of insufficiency, and all patients with a greater degree of insufficiency were excluded from the study. The data obtained during the evaluation of each patient undergoing cardiac catheterization were reviewed by three cardiologists and then entered into a computerized information system in a manner previously described.[7]

Echocardiography: Each of the patients in Group IV underwent two dimensional real time, phased array echocardiography. The two dimensional echographic appearance of the mitral valve leaflets, systolic mitral ring motion and adjacent left ventricular wall motion was analyzed. The presence of mitral valve prolapse was established using criteria described by Gilbert et al.,[9] and included: (1) posteriorly displaced coaptation of the leaflets during systole, (2) superior movement of one or both leaflets during systole above the level of the mitral anulus, and (3) systolic curling motion of the posterior mitral ring on adjacent myocardium.

Radionuclide angiocardiography: Each patient in the study underwent radionuclide angiocardiography at rest and during exercise by a standard protocol. The Baird System Seventy-Seven multicrystal computerized gamma camera was used to acquire and analyze the data obtained in the anterior projection with each patient seated on an isokinetic bicycle ergometer.[6,10] After acquisition of the data at rest, exercise was begun and a second radionuclide angiocardiogram was obtained when 85 percent of the maximal age-predicted heart rate (target heart rate) was achieved, or earlier if symptoms or electrocardiographic changes suggestive of ischemia precluded further exercise.

Variables measured with this technique from which the hemodynamic values were derived included left ventricular ejection fraction and end-diastolic volume. After background subtraction, the ejection fraction was determined from the change in counts from end-diastole to end-systole when peak radioactivity was within the left ventricle. Data recorded from several individual cardiac cycles permit construction of an

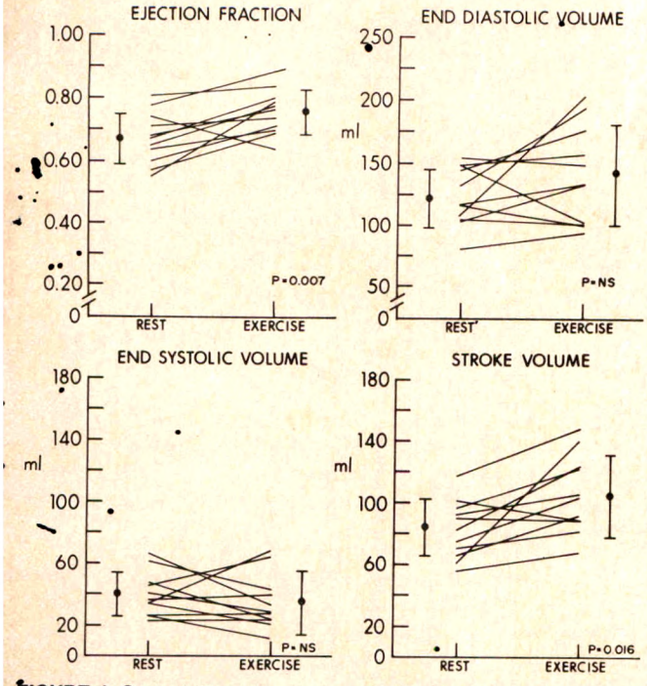

FIGURE 1. Group I. Response to exercise in 11 patients with normal coronary anatomy and no mitral valve prolapse. During exercise, the ejection fraction and stroke volume increased. NS = not significant; p = probability.

average or representative cardiac cycle. The images of the representative cardiac cycle are displayed in a static and cine format for assessment of wall motion. Planimetry of the perimeter and measurement of the major axis of the end-diastolic image of the left ventricle permitted end-diastolic volume determination with the formula of Dodge et al.[11] The stroke volume, end-systolic volume and cardiac output were derived from the ejection fraction and end-diastolic volume. Differences in left ventricular function during rest and exercise assessed with radionuclide angiocardiographic techniques were compared using the paired t test within the groups and the analysis of variance test between the groups. A probability (p) value of less than 0.05 was considered significant.

Results

Comparison of normal patients with patients with mitral valve prolapse: Each of the 11 normal patients (Group I) exercised to a heart rate beyond 85 percent of the age-predicted heart rate, and the average rate increased from 86 ± 17 beats/min at rest to 161 ± 17 beats/min during exercise. The mean blood pressure increased from 97 ± 11 mm Hg at rest to 111 ± 16 mm Hg during exercise. The average ejection fraction of the group increased (0.67 ± 0.08 to 0.76 ± 0.07), and only one patient had a decreased ejection fraction with exercise (Fig. 1). The end-diastolic volume increased (123 ± 24 to 140 ± 39 ml) and end-systolic volume decreased (40 ± 14 to 35 ± 20 ml during exercise. Exercise induced increases were documented in stroke volume (82 ± 19 to 105 ± 26 ml) and cardiac output (7.1 ± 2.4 to 16.8 ± 3.9 liters/min). There were no wall motion abnormalities during rest or exercise.

Changes in ventricular function during exercise in patients with mitral valve prolapse and normal coronary arteriograms (Group II) were similar to those in patients in Group I (Fig. 2). Eight of the 12 patients achieved or exceeded target heart rate during exercise, and the group change in rate from resting conditions to exercise was 89 ± 18 to 154 ± 14 beats/min. The mean blood pressure at rest was 100 ± 12 mm Hg and during exercise was 111 ± 16 mm Hg. Ejection fraction in-

creased with exercise in each patient, and the average increased from 0.61 ± 0.07 to 0.71 ± 0.07. The end-diastolic volume increased (99 ± 27 to 132 ± 49 ml) from rest to exercise; the end-systolic volume was unchanged (39 ± 15 versus 38 ± 19 ml). The stroke volume increased (60 ± 15 to 94 ± 35 ml), and the cardiac output increased (5.2 ± 1.1 to 14.4 ± 5.6 liters/min) during exercise. No patient in this group demonstrated wall motion abnormalities during rest or exercise.

The radionuclide angiocardiographic data of the patients with mitral valve prolapse and normal coronary anatomy (Group II) were compared with data in the patients without mitral valve prolapse and normal coronary anatomy (Group I) (Table I). Significant differences existed only during rest, and these differences were small and appeared to reflect the larger proportion of men in Group I. The end-diastolic volume, stroke volume and cardiac output during rest were greater in the group with normal coronary anatomy and no mitral valve prolapse. All differences disappeared during exercise, and patients with mitral valve prolapse had a response to exercise that could not be distinguished from that in the normal subjects.

Comparison of patients with mitral valve prolapse with and without coronary artery disease: The changes in ventricular function from rest to exercise in patients with coronary artery disease and mitral valve prolapse (Group III) differed from those in the other three groups (Fig. 3). Only 1 of the 11 patients achieved 85 percent of the age-predicted heart rate during exercise. This group had an average heart rate of 79 ± 18 beats/min at rest that increased to only 124 ± 22 beats/min during exercise. The average ejection fraction did not change from rest (0.60 ± 0.07) to exercise (0.58 ± 0.07), and 6 of the 11 patients had a decreased ejection fraction during exercise. The end-diastolic volume (114 ± 33 to 165 ± 44 ml), and end-systolic volume (47 ± 16 to 70 ± 28 ml) increased with exercise as did stroke volume (68 ± 19 to 95 ± 22 ml) and cardiac output (5.1 ± 0.8 to 11.6 ± 2.8 liters/min). One patient had a wall motion abnormality during rest that persisted during exercise, and six patients exhibited new wall motion abnormalities during exercise.

Comparison of the radionuclide angiocardiographic data in the patients with mitral valve prolapse and normal coronary anatomy (Group II) with those of the patients with mitral valve prolapse and significant coronary artery disease (Group III) documented important hemodynamic differences (Table II). The two groups were not different at rest, and the differences between these two groups developed only during exercise. During exercise to a lower heart rate, the group with mitral valve prolapse and coronary disease (Group III) had a lower ejection fraction and a larger end-systolic volume than did Group II.

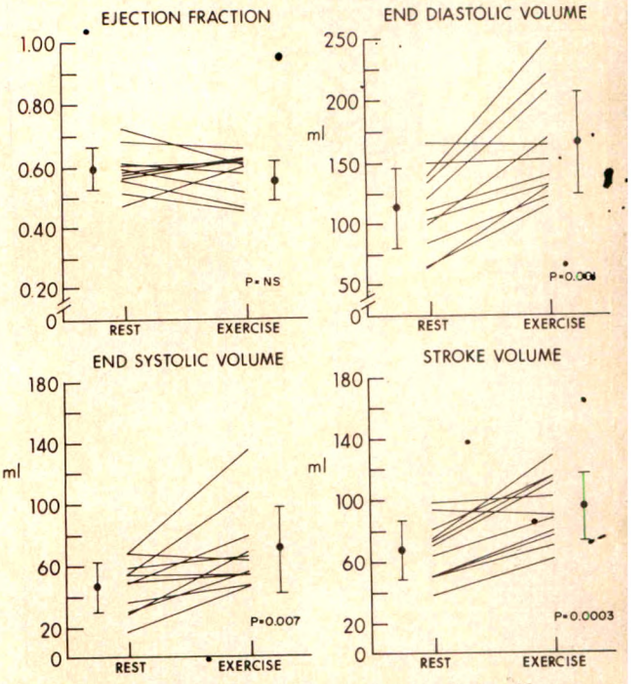

FIGURE 3. Group III. Effects of exercise in 11 patients with coronary artery disease and mitral valve prolapse. The ejection fraction decreased in six patients in whom wall motion abnormalities developed with exercise.

Comparison of patients with mitral valve prolapse diagnosed with angiocardiography and echocardiography: The changes in ventricular function with exercise in patients with echocardiographic documentation of mitral valve prolapse (Group IV) were similar to those in patients with prolapse and normal coronary anatomy (Group II) (Fig. 4). Seven of the 11 patients achieved 85 percent of the age-predicted target heart rate, and the mean heart rate increased from 9[illegible] ± 24 beats/min at rest to 152 ± 16 beats/min during exercise. The change in blood pressure from rest to exercise was 91 ± 9 to 101 ± 13 mm Hg. The average ejection fraction increased during exercise (0.67 ± 0.0[illegible] to 0.73 ± 0.07), and only one patient had a decrease in ejection fraction during exercise. The end-diastolic volume increased during exercise (106 ± 36 to 117 ± 4[illegible] ml); end-systolic volume was not changed from rest t[illegible]

TABLE II

* Group II, patients with mitral valve prolapse and normal coronary angiograms; Group III, patients with mitral valve prolapse and coronary arterial stenosis on angiography. Abbreviations as in Table I.

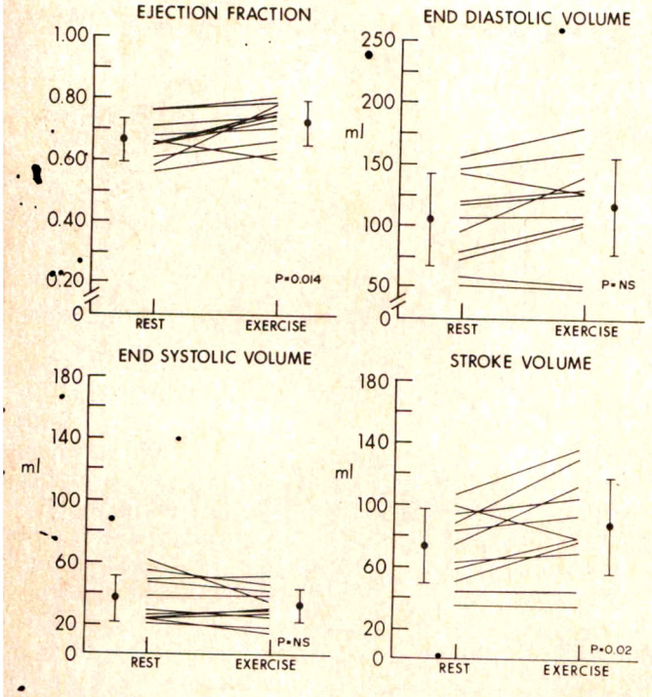

FIGURE 4. Group IV. Response to exercise in 11 patients with mitral valve prolapse diagnosed by echocardiography. The ejection fraction and stroke volume increased with exercise.

exercise (35 ± 15 to 31 ± 11 ml). Stroke volume (71 ± 24 to 86 ± 32 ml) and cardiac output (6.3 ± 2.0 to 13.0 ± 5.2 liters/min) increased during exercise. No patient in Group IV demonstrated wall motion abnormalities during rest or exercise.

Differences in radionuclide angiocardiographic results between the patients with mitral valve prolapse on echocardiography (Group IV) and those with mitral valve prolapse and normal coronary anatomy (Group II) were apparent only during rest (Table III). During rest, the patients with mitral valve prolapse on echocardiography had a lower mean blood pressure that probably reflects the younger age of this group. During exercise, there were no differences between these two groups in any hemodynamic measurement.

Discussion

Since the clinical description of the mitral valve prolapse syndrome by Barlow et al.,[12,13] the cause of the prolapse and its relation to ventricular function have repeatedly been examined.[1,2,14] Left ventricular hemodynamic measurements in patients at rest are frequently normal or reflect the pathophysiology of mitral regurgitation.[1,15,16] Stress-induced myocardial perfusion abnormalities have been documented in patients with mitral valve prolapse, but most of these patients also had coronary artery disease.[17–19] However, changes in ventricular function from rest to exercise in patients with mitral valve prolapse alone and in patients with concomitant coronary artery disease have not been examined.

Exercise-induced changes in left ventricular function demonstrated by radionuclide angiocardiography are sensitive and specific indicators of myocardial ischemia secondary to coronary artery disease.[20] Regions of myocardium that become ischemic during exercise result in wall motion abnormalities and a decrease in global ejection fraction.[5,6,21,22] False negative radionuclide angiocardiographic results occur most frequently in patients with single vessel coronary disease and in patients who fail to achieve an adequate exercise level.

Recognition of mitral valve prolapse by angiocardiography versus echocardiography: The purpose of this investigation was to assess (1) whether hemodynamic alterations could be measured during exercise in patients with mitral valve prolapse alone, and (2) whether these patients could be differentiated from a similar group of patients with mitral valve prolapse and concomitant coronary artery disease. Isolation of these homogeneous patient populations required retrospective review of studies in a large number of patients. Whereas it would have been ideal to have patient populations with mitral valve prolapse documented with both cardiac catheterization and echocardiography, very few patients met these criteria. The patients with mitral valve prolapse diagnosed with echocardiography (Group IV) differed from those whose diagnosis was made by cardiac catheterization in that the age and presenting symptoms of the former patients were not strongly suggestive of coronary artery disease. Therefore, confirmation of the clinical diagnosis of mitral valve prolapse by echocardiography commonly completed the diagnostic evaluation and cardiac catheterization was not recommended. In contrast, the diagnostic consideration of coronary artery disease was the primary motivation for cardiac catheterization in patients in Groups I, II and III, and cardiac catheterization was commonly the final step in evaluation of these patients.

Although it is not possible to state definitely that patients in Group IV had no coronary artery disease, the similar response to exercise in Groups II and IV suggests

TABLE. III

Comparison of Groups II and IV* by Analysis of Variance

Ex	NS	NS	NS	NS	NS	NS	NS

* Group II, patients with mitral valve prolapse and normal coronary angiograms. Group IV, patients with mitral valve prolapse on echocardiography but no other demonstrable cardiac disease. Abbreviations as in Table I.

the absence of significant disease. If differences had occurred between these two groups, it would not be possible to conclude whether the cause was the presence of coexistent coronary artery disease in Group IV or the differences in patients diagnosed to have prolapse by angiographic or echocardiographic criteria. The absence of significant hemodynamic changes in the two groups during rest and exercise is strong evidence that recognition of mitral valve prolapse by either diagnostic modality is not associated with hemodynamic alteration that can be recognized by radionuclide measurements of left ventricular function at rest or exercise.

Radionuclide angiocardiography in differentiating mitral valve prolapse with or without coronary artery disease: Stress myocardial scintigraphy using thallium-201 has been observed to differentiate patients with mitral valve prolapse syndrome from those with coronary artery disease and mitral valve prolapse.[17,19] This study suggests that the two disease entities can also be differentiated by changes in ventricular function from rest to exercise determined with radionuclide angiocardiography. Each of the 11 patients with normal coronary anatomy and mitral valve prolapse demonstrated changes in ventricular function similar to those in patients with normal coronary anatomy and no mitral valve prolapse. During exercise, the ejection fraction increased, and no wall motion abnormalities developed in both groups. Therefore, the presence of mitral valve prolapse alone caused no measurable detrimental effect on ventricular function during rest or exercise.[23] In contrast, changes in ventricular function with exercise in patients with concomitant mitral valve prolapse and coronary disease appear to reflect the presence and severity of the coronary artery disease rather than prolapse. Although only 1 of the 11 patients with both diseases achieved an adequate exercise level, 6 had a decreased ejection fraction and exhibited wall motion abnormalities with exercise.

Implications: Changes in ventricular function from rest to exercise assessed with radionuclide angiocardiography can distinguish patients with mitral valve prolapse alone from those with prolapse and coronary artery disease. Patients with mitral valve prolapse alone had uniform increases in ejection fraction and no wall motion abnormalities with exercise, whereas patients with both prolapse and coronary disease frequently demonstrated decreased ejection fraction and wall motion abnormalities provoked during a lower exercise level. Therefore, exercise-induced decreases in ejection fraction and wall motion abnormalities in patients with prolapse diagnosed with echocardiography would suggest the presence of concomitant significant coronary disease.

To test the feasibility of detecting transient left ventricular regional wall motion abnormalities during exercise-induced myocardial ischemia, 55 patients undergoing diagnostic coronary arteriography were studied in a prospective blinded manner with wide angle cross-sectional echocardiography. The ultrasonic studies were obtained with the patients at rest and during exercise in the supine position using a bicycle ergometer. Cross-sectional echocardiographic studies during exercise were adequate for analysis in 43 (78 percent) of the 55 patients. Forty-one of the 43 manifested either a new regional wall motion abnormality during exercise (20 subjects) or wall motion that remained entirely normal during exercise (21 subjects); in two subjects an abnormal wall motion abnormality at rest did not change with exercise. Nineteen of the 20 patients with a new regional wall motion abnormality had significant coronary artery disease and 15 of these 19 had S-T segment depression during bicycle ergometry. The one patient with a normal coronary arteriogram had an early cardiomyopathy. Ten of the 21 subjects with normal wall motion at rest and during exercise had a normal coronary arteriogram, whereas 11 had evidence of important anatomic coronary artery disease and thus had a false negative echocardiographic findings. Six of these 11 patients had S-T segment depression during exercise. The usefulness of exercise echocardiography to predict coronary artery disease was not altered even when only 26 patients without previous myocardial infarction and with a normal cross-sectional echocardiogram at rest were considered. Thus, new regional wall motion abnormalities during exercise as identified with cross-sectional echocardiography represent a specific finding for the presence of coronary artery disease. However, normal regional wall motion during exercise does not exclude the presence of important anatomic coronary artery disease.

Echocardiography has been used as a reliable method of detecting myocardial ischemia or infarction, or both, by demonstrating regional left ventricular wall motion abnormality at rest.[1–3] However, without prior myocardial infarction or acute ischemia, patients with severely obstructed coronary arteries frequently have normal left ventricular wall motion at rest.[4,5] During exercise, increased oxygen demand may outstrip the limited supply from a diseased coronary artery, thus precipitating acute myocardial ischemia with associated abnormal regional wall motion.[6–9] New regional wall motion abnormalities as a sign of coronary artery disease were demonstrated during exercise-induced ischemia with left ventricular cineangiography[10,11] and cardiac nuclear imaging techniques.[12,13] Studies[14–16] during acute coronary arterial ligation in the dog showed that, with the onset of ischemia, rapid deterioration of regional wall motion occurred even before the development of S-T segment changes in the electrocardiogram. These myocardial alterations were immediately reversible on release of the coronary ligature.

The potential for using exercise as a means of inducing regional wall motion abnormalities while imaging the heart with echocardiography

was reported by Mason et al.,[8] using the M mode technique. Unfortunately, this technique is limited in the extent of myocardium that can be imaged; and only 45 percent of their studies were considered adequate for analysis. The use of cross-sectional echocardiography to detect regional wall motion abnormality provides a better visual orientation and was recently explored by Wann et al.[9] However, their study was limited to a 30° mechanical sector scan of the myocardium in which endocardial images were not well demonstrated. In this study we attempted to test the feasibility of detecting transient left ventricular regional wall motion abnormalities during exercise-induced myocardial ischemia using wide angle cross-sectional echocardiography to predict the presence of coronary artery disease.

Methods

Patients: Fifty-five patients, 40 men and 15 women with a mean age (± standard deviation) of 52 ± 11 years undergoing diagnostic coronary arteriography were studied in a prospective blinded manner. All patients had a clinical chest pain syndrome considered consistent with angina pectoris. Patients who had a recent myocardial infarction, valvular heart disease, unstable angina pectoris, congestive heart failure or overt arrhythmia were excluded primarily because exercise testing would have been inadvisable under these conditions. Evidence of prior myocardial infarction (3 or more months) by 12 lead scalar electrocardiography was present in 18 of the 55 patients.

Echocardiographic technique: Cross-sectional and M mode echocardiograms were obtained within 24 hours before cardiac catheterization with use of a wide angle, three element rotary mechanical sector scanner (ATL Mark III). A standard cross-sectional echocardiographic study was obtained at rest in which the left ventricular long axis, multiple short axis and apical views of the left ventricle were imaged. Patients exercised in the supine position using a bicycle ergometer (Quinton Imaging Ergometer Table 845T) with the patient's upper torso and head held fixed by restraints. Exercise was performed at an initial work load of 200 kg.m/min. for 3 minutes with an increase of 100 kg.m every 3 minutes. The test was stopped because of the development of chest pain, 2 mm or greater S-T segment depression or exhaustion. A full 12 lead electrocardiogram (Marquette Electronics, Inc., Milwaukee, Wisconsin) and sphygmomanometer-determined blood pressure were recorded each minute throughout the test. During exercise the echocardiographic transducer was constantly held on the patient's precordium in order to visualize primarily the short axis view of the left ventricle from the level of the mitral valve through that of the cardiac apex. During peak exercise the transducer was rotated to visualize the long axis and apical four chamber left ventricular views.

Cross-sectional echocardiograms were recorded on a Sanyo (model 7100) 0.5 inch (1.27 cm) videotape recorder and were later analyzed by three independent observers without knowledge of the clinical findings or cardiac catheterization data. There was concordant interobserver analysis in 95 percent of cases. Intraobserver variability was not tested. Figure 1 depicts the left ventricular walls seen in each echocardiographic view in which motion was qualitatively analyzed. Abnormal wall motion was identified by comparing the wall motion of that particular segment with that of all other segments of the heart and was graded as hypokinetic, akinetic or normal.

Cardiac catheterization: Left ventriculography was performed using either the Sones or Judkins technique in the right anterior oblique position. Coronary angiograms were analyzed by two independent observers for the degree of stenosis of the right, left main, left anterior descending and left circumflex (or its marginal branch) coronary artery. A vessel was considered to have important obstruction if 50 percent or more of its lumen was narrowed in diameter.

Results

Our technique of exercise cross-sectional echocardiography required approximately 1 hour to complete from preparation through the patient recovery period. Cross-sectional echocardiographic studies during exercise were adequate for analysis in 43 (78 percent) of the 55 patients. The mean age of these 43 patients was 51 ± 11 years and 29 were men. Eleven of the 12 inadequate studies were in men whose mean age was 57 ± 6 years (Table I). The major technical limitation during

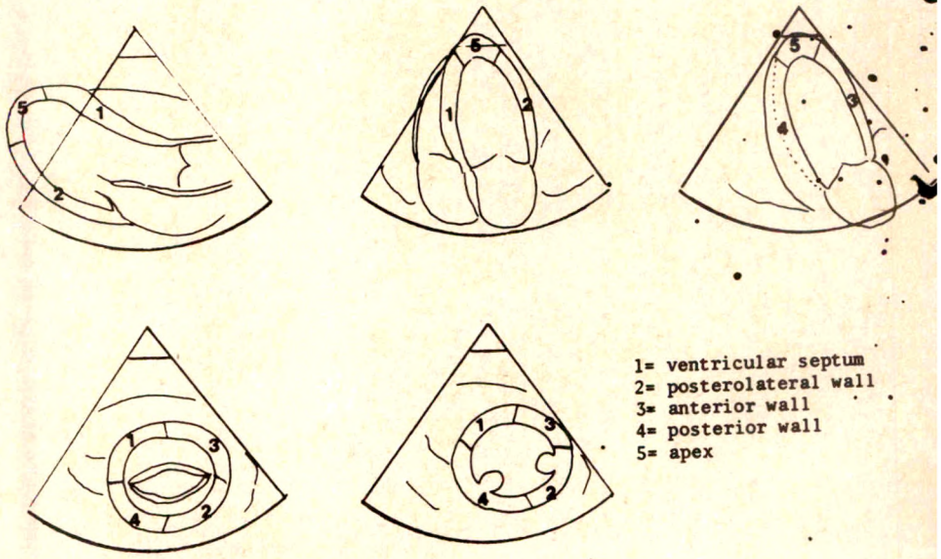

FIGURE 1. Schematic drawings representing **(from upper left to lower right)** the left ventricular long axis, apical four chamber, apical two chamber and short axis views, first at the mitral valve and then at the papillary muscle level, demonstrating the location of the left ventricular wall segments used during data analysis.

exercise was hyperventilation because the motion of the upper thorax was held stationary by the use of restraints. Exercise studies primarily focused on data from the sternal approach to the short axis of the left ventricular scanning from the level of the mitral valve to that of the cardiac apex because these views provided the best endocardial definition. Patients receiving propranolol therapy are listed in Table I.

Wall motion at rest and during exercise: Comparison of the resting cross-sectional echocardiogram with the single plane right anterior oblique left ventricular angiogram revealed that both studies showed normal regional wall motion in 23 patients and abnormal regional wall motion in 9 patients. A normal resting echocardiogram but mildly abnormal ventriculogram (showing hypokinesia) was seen in nine subjects (anterior wall in five, posterior in three and diffuse in one). In two subjects the ventriculogram was normal at rest but posterior hypokinesia was evident in the echocardiogram at rest.

Forty-one of the 43 subjects with adequate studies had either a new or increased regional wall motion abnormality during exercise (n = 20) or the wall motion remained entirely normal during exercise (n = 21). Two subjects (Patients 22 and 24) had abnormal resting left ventricular wall motion that did not change during exercise echocardiography; both patients had significant coronary artery disease.

* Occult idiopathic congestive cardiomyopathy on left ventricular angiography.

A = anterior wall; CAD = coronary artery disease; MI = myocardial infarction; NI = normal wall motion; P = posterior wall; PL = posterolateral wall; S-T↓ = mm of S-T segment depression during supine ergometry; VS = ventricular septum ↓ = hypokinetic; ↓↓ = akinetic; + = present; − = absent.

Correlation with coronary arteriographic findings: Twenty of 41 patients had a new regional wall motion abnormality on cross-sectional echocardiography during exercise and 19 of the 20 had significant coronary artery disease (three vessel disease in 11, two vessel disease in 4, and one vessel disease in 4). Fifteen of these 19 patients had S-T segment depression during bicycle ergometry, whereas 4 did not. The one patient with a normal coronary arteriogram had evidence of an early cardiomyopathy on left ventricular cineangiography with diffuse hypokinesia and an elevated left ventricular end-diastolic pressure.

Twenty-one of the 41 patients had normal left ventricular wall motion on echocardiography at rest and during exercise. Ten (48 percent) of these 21 patients had a normal coronary arteriogram; 9 had no S-T segment abnormalities on exercise, and the other patient had 2 mm S-T segment depression. Eleven (52 percent) of the 21 patients had important anatomic coronary artery disease and thus had a false negative echocardiographic response. Six of the 11 had S-T segment depression during exercise, whereas 5 did not. Four of the 11 patients had three vessel, 5 had two vessel and 2 had one vessel coronary artery disease. Figures 2 and 3 show a normal echocardiographic study at rest and during exercise, respectively, a patient with normal coronary angiographic findings and a patient with three vessel coronary artery disease (false negative response). Figure 4 demonstrates the echocardiogram of a patient who manifested a new regional wall motion abnormality on exercise and who had coronary artery disease (true positive response).

Correlation in patient group without previous myocardial infarction: The overall results were not altered when only the 26 patients with adequate cross-sectional echocardiograms, no prior myocardial infarction and a normal cross-sectional echocardiogram at rest were studied. Nine of the 26 had a new regional wall motion abnormality on exercise, and 8 of these 9 had significant coronary artery disease (4 had three vessel, 2 had two vessel and 2 had one vessel disease). Of these eight patients, six had S-T segment depression induced with bicycle ergometry and two did not. Once again one patient had normal coronary angiographic findings and his new regional wall motion abnormality was judged to be caused by an early cardiomyopathic

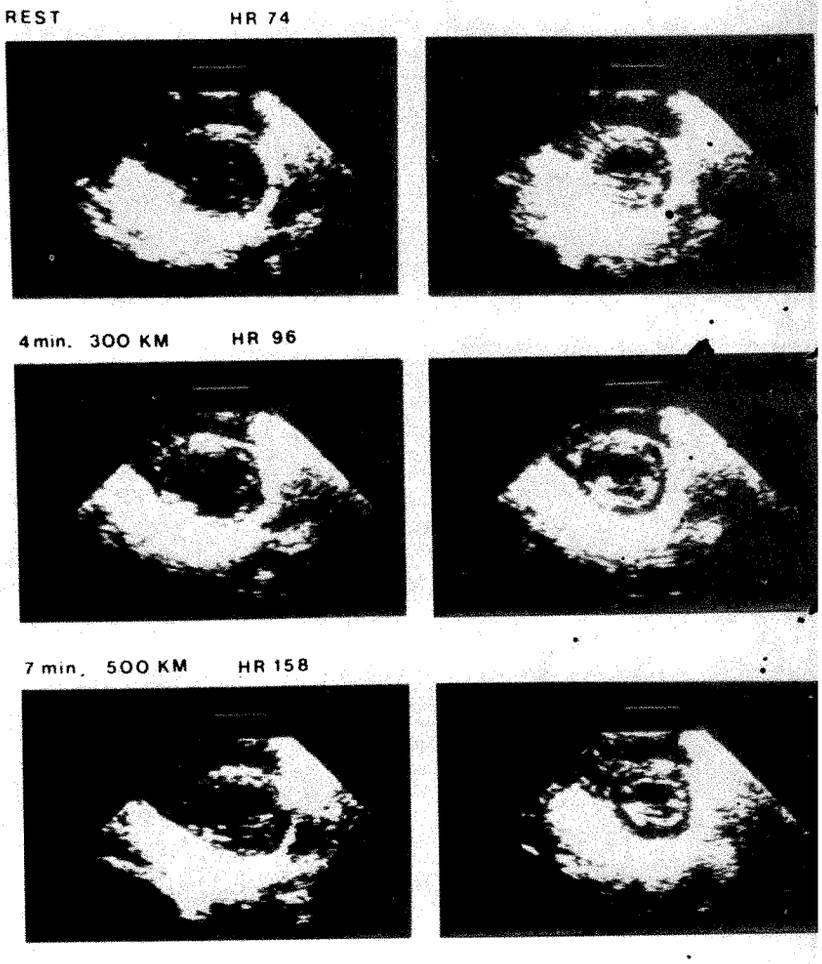

FIGURE 2. Left ventricular short axis views during end-diastole (**left panels**) and end-systole (**right panels**) in a patient with normal coronary arteriographic findings. The echocardiographic studies were taken at rest (heart rate [HR] 74 beats/min) and during supine ergometry first at 4 minutes at a work load of 300 kg.m and then at 7 minutes at a work load of 500 kg.m. Note that there is normal contraction during systole of all left ventricular wall segments and that qualitatively the end-systolic volume was decreased at peak exercise compared with the resting state, suggesting an increase in regional ejection fraction.

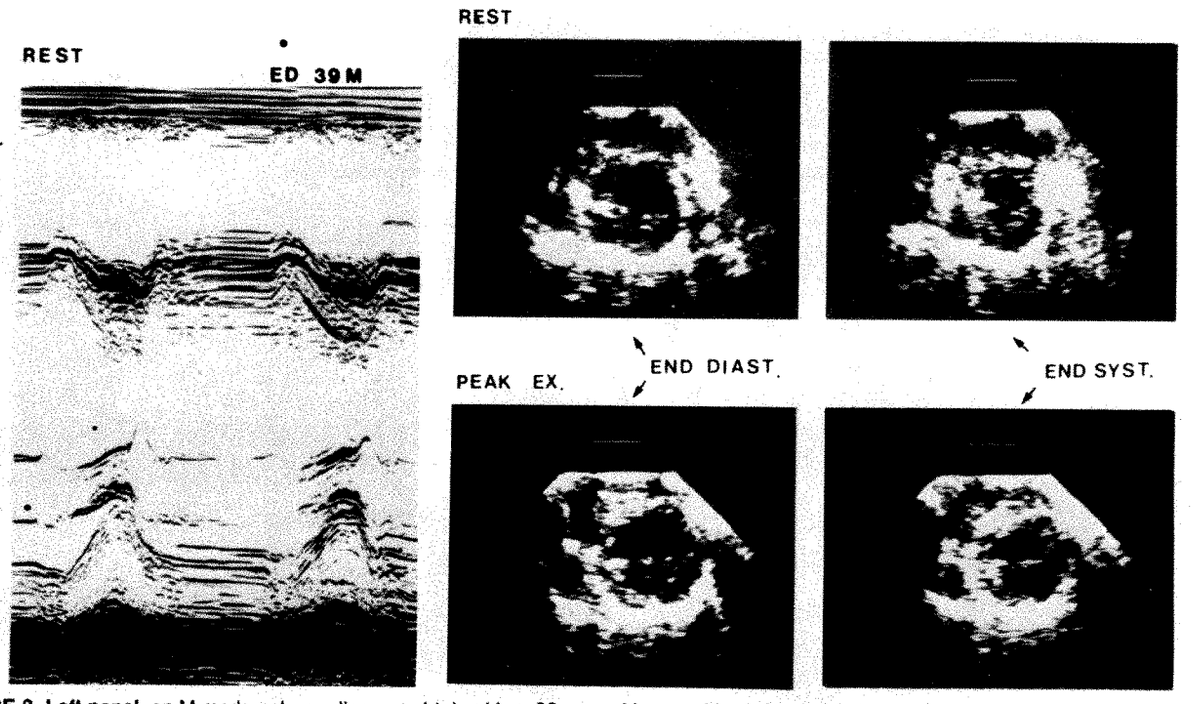

FIGURE 3. Left panel, an M mode echocardiogram obtained in a 39 year old man with angina pectoris and three vessel coronary artery disease demonstrating at rest normal ventricular septal and posterior left ventricular wall motion. **Right panel,** left ventricular short axis views at the level of the papillary muscles demonstrating end-diastole (DIAST.) on the left and end-systole (SYST.) on the right. Left ventricular wall motion remained normal at rest and during exercise (EX).

state. Seventeen of the 26 patients had normal cross-sectional echocardiogram at rest and during exercise. Ten (59 percent) of the 17 had a normal coronary arteriogram, including 9 who had no abnormality in the S-T segment response to ergometry. The other seven (41 percent) had coronary artery disease (three vessel in one, two vessel in four and one vessel in two) and four of the seven had S-T segment depression on bicycle ergometry. These patients therefore had a false negative response. Thus, with exclusion of regional wall motion abnormalities at rest or prior myocardial infarction, the percent of false negative responses changed from 52 to 41 percent.

Discussion

In the classic study by Tennant and Wiggers,[17] acute coronary arterial ligation in the dog produced immediate abnormal contraction of the left ventricular myocardial segment supplied by that coronary artery. This has been shown with a wide variety of techniques[1–9] to occur in human beings during acute ischemia and acute myocardial infarction. The mechanical abnormalities with ischemia occur within seconds and disappear rapidly with reversal of ischemia.[14–16] Both exercise cineangiography and cardiac nuclear imaging techniques have demonstrated new areas of left ventricular wall motion abnormality during acute ischemia that disappear rapidly after ischemia is reversed. M mode echocardiography has been limited because of its relatively narrow view of the myocardium and small proportion of adequate studies. Two dimensional echocardiography provides the ability to view the major area of the myocardium during exercise and approximately 75 percent of these studies are adequate for analysis. This is a higher proportion than that reported for M mode echocardiography probably because of the better spatial orientation and more easily identified landmarks during two dimensional echocardiography. The increased field of view of the wide angle two dimensional echocardiographic equipment as used in this study allows for a more precise identification of regional wall motion abnormalities than is possible with M mode echocardiography or narrow two dimensional echocardiographic sector scanners.

Sensitivity of two dimensional echocardiography on exercise: The results of our study, similar to those of Wann et al.,[9] demonstrate that patients who manifest new regional wall motion abnormalities during exercise invariably have coronary artery disease. However, one patient (5 percent) did have left ventricular regional wall motion abnormalities probably because of an occult cardiomyopathy rather than coronary artery disease. Although abnormal regional wall motion on two dimensional echocardiography during exercise appeared to be highly specific for the presence of coronary artery disease, its absence did not predict a high likelihood of a normal coronary arteriogram. About 50 percent of our patients with normal regional wall motion during exercise had important anatomic coronary artery disease. Thallium-201 myocardial perfusion scanning was not

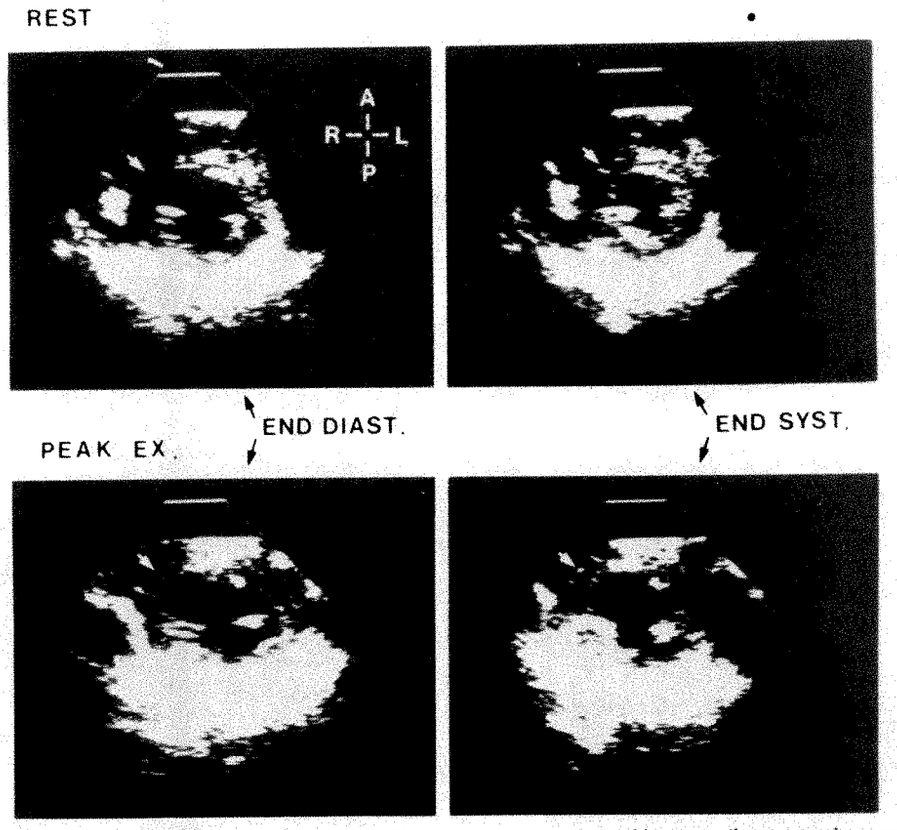

FIGURE 4. Left ventricular short axis views at the level of the papillary muscle in a patient with severe three vessel coronary artery disease and angina pectoris depicting end-diastole (DIAST.) at left and end-systole (SYST.) at right. The **small white arrow** points to the ventricular septum, which has normal motion during systole in the resting state, but becomes akinetic during peak exercise (EX.). The apparent increase in end-systolic volume during peak exercise suggests a decrease in regional ejection fraction.

available in these patients to permit determination of whether the coronary obstructive disease, although anatomically important, was associated with a myocardial perfusion deficit. However, approximately 50 percent of these patients had abnormal S-T segment depression during exercise testing. Thus, it appeared that the electrocardiographic manifestation of ischemia in these patients was more sensitive in predicting the presence of anatomic coronary artery disease than was the presence of new regional wall motion abnormalities on two dimensional echocardiography during exercise. This is in distinct contrast to a much higher sensitivity for the prediction of coronary artery disease by detecting abnormal regional wall motion during exercise radionuclide studies.[12]

Our results were not altered when those patients with resting regional wall motion abnormality on echocardiography were excluded or when the use of propranolol was considered. Of the 14 patients receiving propranolol, 10 had a new regional wall motion abnormality on exercise; 9 of these had coronary artery disease and the other an occult cardiomyopathy. The other four patients had no new regional wall motion abnormality during exercise echocardiography, even though they all had coronary artery disease.

The exercise protocol used in this echocardiographic study relied on the supine rather than the upright position which is commonly used for the standard treadmill exercise test. The supine position was considered adequate to induce ischemia because it is associated with a sufficient increase in blood pressure and heart rate to induce ischemia.[18] Similar protocols are used in radionuclide angiography and, thus, the variance in sensitivity between two dimensional echocardiography and radionuclide angiography cannot be explained by the degree or type of exercise employed. Relative limitations of two dimensional echocardiography in viewing the entire ventricle at once (which can be done by radionuclide angiography) is a potential factor.

Clinical implications: Because two dimensional exercise echocardiography is noninvasive, easily repeatable and inexpensive, determines instantaneous events and does not impose a potential radiation hazard, it may prove to have a useful role in the noninvasive detection of coronary artery disease. It appears to identify new regional wall motion abnormalities during exercise that, when present, specifically indicate the presence of coronary artery disease. However, it may show normal findings in about 50 percent of patients with such disease.

The importance of the coronary collateral circulation as a cause of false negative exercise tests was studied in 37 patients who had a 90 percent or greater isolated stenosis of the luminal diameter in one major coronary artery. Sixteen patients had large collateral vessels and 21 patients had either minimal or no collateral circulation. Myocardial scintigraphy was performed in 22 of the 37 patients.

The final treadmill time was similar in both groups (521 ± 192 versus 554 ± 144 seconds [mean ± standard error of the mean]). The presence and depth of S-T segment depression was not influenced by the degree of collateralization. The sensitivity of the exercise electrocardiogram was greater for patients with disease in the left anterior descending than in the right or left circumflex coronary arteries (95 versus 60 percent, $p < 0.03$). Among the 22 patients with thallium-201 scintigrams, myocardial perfusion defects were more common in patients without collateral circulation (100 versus 40 percent, $p < 0.01$) and involved more myocardial segments ($p < 0.005$). The overall sensitivity of exercise electrocardiography for the detection of single vessel stenosis 90 percent or greater was similar to that of myocardial scintigraphy (81 versus 73 percent).

In conclusion, large intercoronary collateral vessels are not a cause of false negative exercise electrocardiograms in patients with single vessel disease but are a common cause of false negative scintigrams. Large collateral vessels may limit the quantity and location of myocardial ischemia, but exercise electrocardiography and thallium-201 scintigraphy may detect different aspects of ischemia.

Single vessel coronary artery disease is a common cause of false negative results in diagnostic stress testing.[1–6] The addition of thallium-201 scintigraphy to such testing has increased the detection of patients with single vessel disease but false negative results are still common in patients with isolated right or left circumflex coronary artery disease.[7–14] There are few data that evaluate the role of the coronary collateral circulation as a possible cause of false negative tests. Clearly, if large well developed collateral vessels distal to a high grade coronary arterial stenosis could prevent or rapidly reverse transient myocardial ischemia, no significant electrocardiographic changes or perfusion defects would be observed. This study examines the hypothesis that coronary collateral circulation can cause false negative exercise electrocardiograms and myocardial scintigrams.

Methods

Study patients: The study group consisted of 37 patients with single coronary arterial stenosis equal to or greater than 90 percent of the luminal diameter in one of the three major coronary arteries and no other arterial stenosis of 50 percent or greater. All patients had chest pain for at least 6 months before cardiac catheterization. There were 26 men and 11 women whose mean age was 47 years (range 26 to 62). Patients with a previous myocardial infarction, cardiomyopathy or valvular heart disease were excluded.

Electrocardiographic exercise test: Each patient underwent a maximal symptom-limited stress test performed with use of 14 electrocardiographic leads according to a modified Bruce protocol.[15,16] A test was considered positive if horizontal or downsloping S-T segment depression of 1 mm or more or a slow upsloping S-T segment depressed 2 mm or more at 0.08 second after the J point occurred.[15–17] All patients with a negative test achieved at least 85 percent of their age-predicted maximal heart rate.

Myocardial scintigraphy: Myocardial scintigraphy was performed in 22 of the 37 patients after 2 millicuries (mCi) of thallium-201 was injected intravenously 45 to 60 seconds before terminating exercise. Anteroposterior, 30° left anterior oblique and left lateral views were obtained using standard techniques. The total of 150,000 counts/view over the left ventricle were registered with a Picker-Dyna 4/5 gamma camera equipped with a high resolution collimator and a 20 percent window. Counts originating from the spleen or liver were avoided using a 12 cm leaded mask. The scintigrams were photographed in black and white on 70 mm film after 30 percent background subtraction and a 9 point matrix smoothing. The scintigram at rest was obtained 4 to 10 days after exercise.

The scintigrams were interpreted qualitatively by three observers unaware of the clinical status, exercise test results or location of the diseased vessel. The test was considered positive if a localized reversible perfusion defect was present. The extent of the defect was analyzed semiquantitatively by dividing each scintigram into five segments as described by Rigo et al.[18] The myocardial segments corresponding to each coronary artery were considered in order to quantify the extent of myocardial ischemia.

Assessment of collateral circulation: Coronary angiography was performed using the transfemoral approach.[19] A coronary arterial stenosis of 90 percent or greater of the luminal diameter was considered a significant lesion for the purpose of this study; this degree of narrowing is usually required to demonstrate collateral vessels at angiography. The presence of collateral circulation was assessed by an experienced cardiovascular radiologist unaware of the results of noninvasive testing.[20] The average ejection fraction calculated by the area-length method[21] was 0.62 ± 0.08 (mean ± standard error of the mean).

Statistical analysis: The differences between groups were analyzed using the chi-square test for nonparametric variables and the unpaired *t* test and analysis of variance for parametric variables.

Results

Coronary angiography: Obstructive coronary artery disease (90 percent or greater stenosis of the luminal diameter) was present in the left anterior descending coronary artery in 22 patients, in the left circumflex coronary artery in 5 patients and in the dominant right coronary artery in 10 patients. The patients were classified into two groups on the basis of the degree of collateralization. In group A (n = 16 patients), the distal segment of the stenosed vessel was clearly opacified and large intercoronary collateral vessels were visible. Group B (n = 21 patients) was characterized by minimal or absent collateral blood flow (involving only the interseptal-intermarginal branches).

Exercise electrocardiography: The physiologic limitation to exercise was greatest in patients with left anterior descending arterial stenosis. These patients had a final treadmill exercise time of 481 ± 177 (mean ± standard deviation) seconds versus 626 ± 98 seconds in patients with either right or left circumflex coronary artery disease ($p < 0.05$). Exercise was terminated by angina in 91 percent of patients (20 of 22) with but in only 20 percent of patients (3 of 15) without left anterior descending arterial stenosis ($p < 0.005$). The patients with left anterior descending stenosis of the left anterior descending common artery had more ischemic electrocardiographic responses than did those with right or left circumflex coronary arterial stenosis (95 percent [21 of 22] versus 60 percent [9 of 15]; $p < 0.03$). However, among the 30 patients with a positive electrocardiographic test the number and location of positive leads, depth of S-T segment depression and duration of ischemia after exercise did not correlate with the location of the diseased vessel. Leads V_4 to V_6, CC_5 or CM_5 recorded significant S-T segment depression in the patients with right or left circumflex coronary artery disease.

The presence and depth of S-T segment depression was not influenced by the degree of coronary collateralization (Fig. 1). Of 16 patients in group A (with collateral vessels), 94 percent had a positive electrocardiographic test compared with 71 percent of the 21 patients in group B (without collateral vessels) (difference not significant [NS]). The maximal treadmill time was 521 ± 192 seconds for patients in group A compared with 554 ± 144 seconds in patients in Group B. The maximal pressure-rate product was also similar in both groups. The frequency of angina during exercise was 56 percent (9 of 16) patients in Group A and 67 percent (14 of 21) in patients in group B (difference not significant).

Myocardial scintigraphy: Exercise thallium-201

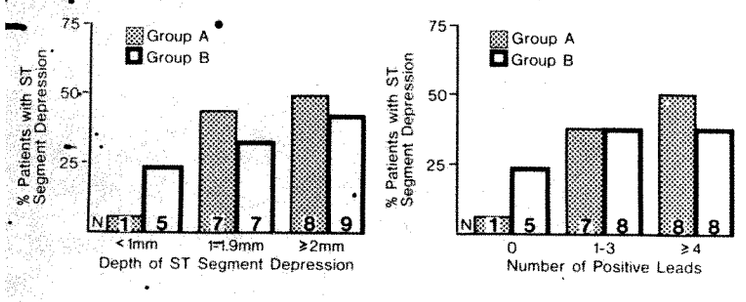

FIGURE 1. The depth of S-T segment depression (**left**) and the number of positive electrocardiographic leads (**right**) was similar in patients with (group A) and without (group B) collateral vessels.

Ant = anterior; Diag = diagonal branch of left anterior descending artery; ex = exercise; HR = heart rate; inf = infero; LAD = left anterior descending coronary artery; lat = lateral; LCx = left circumflex coronary artery; Max = maximal; RCA = right coronary artery; S-T↓ = depression; TT = treadmill time.

scintigrams were performed in 22 patients (Table I). Among the 16 patients with left anterior descending arterial stenosis, 81 percent had a positive scintigram compared with 50 percent of the 6 patients with right or left circumflex coronary artery disease (difference not significant). Myocardial perfusion defects were more common in patients without collateral vessels. All 12 patients in group B had perfusion defects compared with only 40 percent (4 of 10) of patients in group A ($p < 0.01$). The extent of hypoperfusion was larger in patients in group B and frequently involved three or more segments ($p < 0.005$) (Table II). The results were similar in patients with occluded coronary arteries and well developed collateral vessels (Fig. 2). The perfusion defect corresponded to the site of coronary artery disease in 94 percent of the 16 patients with a positive scan (Fig. 3).

Discussion

Exercise electrocardiography: The sensitivity of exercise electrocardiography in the detection of coronary artery disease is decreased in patients with single vessel disease (Table III).[1–6,16] The sensitivity ranges from 33 to 95 percent, reflecting the use of differen

exercise protocols and lead systems, the inclusion of patients with previous myocardial infarction, the location of the diseased vessel and the degree of coronary arterial narrowing required for detection. The higher sensitivity observed in this study results from the presence in all patients of a stenosis of 90 percent or greater of luminal diameter and a normal electrocardiogram and left ventricular contraction pattern at rest.

The sensitivity of exercise electrocardiography was increased in our patients with left anterior descending coronary disease this finding is similar to the results obtained by McHenry et al.[3] but in contrast to the results of other investigators.[4,6] The difference may represent (1) the amount of myocardium that can be rendered potentially ischemic during exercise or (2) the exercise electrocardiographic lead system recorded during and after exercise, or both. A luminal narrowing or less than 75 percent at angiography may not reduce coronary blood flow during exercise by an amount sufficient to show significant differences in the location of the stenosed vessel. Our results suggest that once sufficient muscle has been rendered ischemic to produce an S-T segment shift, the location of the diseased vessel cannot be predicted from the number or location of positive electrocardiographic leads or from the depth of S-T segment depression. Kaplan et al.[6] were also unable to predict the location of single vessel coronary disease in 18 patients who underwent submaximal treadmill tests using leads I, aVF and V_5 or CM_5.[6]

The presence of extensive collateral vessels to the stenosed vessel was not associated with a decreased likelihood of S-T segment depression or an increased work capacity. Similar results have been reported by Martin and McConahay.[2] Thus, extensive collateralization in patients with single vessel disease is not a cause of false negative electrocardiographic results. Decreased sensitivity of the test is related mainly to the degree of coronary arterial narrowing and to the location of the diseased vessel.

Myocardial scintigraphy: The sensitivity of myocardial scintigraphy in detecting single vessel disease (range 43 to 92 percent, Table IV) is greater than that reported for exercise electrocardiography.[7–14] In studies that reported sensitivity according to location of the diseased vessel,[10] perfusion defects were more common when the left anterior descending coronary artery was obstructed. False negative scans were more common in patients with well developed collateral vessels ($p < 0.01$). Similar results were reported by Rigo et al.[18] The patients with large collateral vessels also had smaller perfusion defects than did patients without collateral vessels. Thus, extensive collateralization in patients with single vessel disease is a cause of false negative thallium scans in contrast to exercise electrocardiography, which is largely unaffected by the degree of collateralization.

Limitations of present study: The functional significance of collateral blood vessels in human beings is difficult to evaluate. Several studies have correlated the

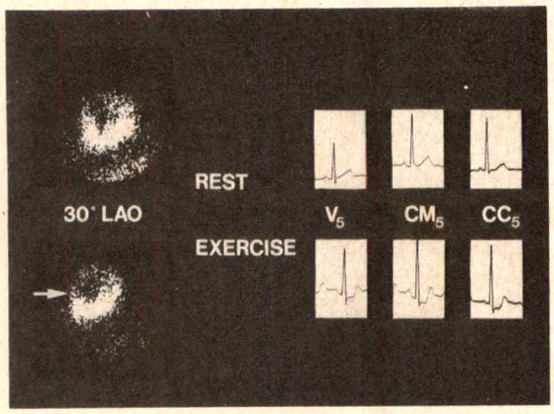

FIGURE 3. Patient 9 (group B). A septal perfusion defect (**arrow**) during exercise is seen in this patient, who had a 95 percent stenosis in the left anterior descending artery and no collateral vessels. The exercise electrocardiogram shows horizontal S-T segment depression in leads V_5, CM_5 and CC_5.

* Sensitivity of 100 percent (7 of 7) for stenosis of left anterior descending artery (LAD), of 86 percent (6 of 7) for stenosis of right coronary artery (RCA), of 25 percent (1 of 4) for stenosis of left circumflex coronary artery (LCx). † Sensitivity of 81 percent (13 of 16) for stenosis of LAD, of 50 percent (2 of 4) for stenosis of RCA and of 50 percent (1 of 2) for stenosis of LCx.

degree of collateralization with wall motion abnormalities and angina but there are few data that correlate the physiologic effects of large collateral vessels visualized on angiography with exercise test results.[20,22–25] Collateral vessels usually become visible when the degree of luminal stenosis exceeds 75 to 90 percent and the collateral channels measure 100 mm or more.[22] Smaller collateral vessels are not visualized with conventional angiographic techniques and consequently could not be assessed in our study. The sensitivity of myocardial scintigraphy for small perfusion defects may be increased with use of the seven pinhole collimator.[26] The radionuclide technique we used in this study is the standard method used in most nuclear medicine laboratories. Collateral blood vessels are more common in patients with multivessel disease[25]; our study group was highly selected. We chose patients with isolated single vessel stenosis of 90 percent or greater to avoid the variable of proximal luminal obstruction that might jeopardize collateral flow and we included no patients with a prior myocardial infarction in order to have a more homogeneous study group. Our results show that collateral vessels can cause false negative thallium scans but do not influence the exercise electrocardiogram. The apparent discrepancy between these two noninvasive tests indicates the importance of the diagnostic approach selected to detect myocardial ischemia.

One possible explanation of this discrepancy is that the coronary collateral circulation can result in nontransmural or subendocardial rather than transmural ischemia. Exercise electrocardiography readily detects subendocardial ischemia, whereas exercise thallium-201 scintigraphy may be more easily defined in the presence of transmural myocardial ischemia. Thus, large collateral vessels may affect the pattern and distribution of myocardial ischemia and both exercise electrocardiography and thallium-201 scintigraphy may reveal different aspects of ischemia.

Lack of Correlation Between Exercise Capacity and Indexes of Resting Left Ventricular Performance in Heart Failure

JOSEPH A. FRANCIOSA, MD, FACC*
MARY PARK
T. BARRY LEVINE, MD

Philadelphia, Pennsylvania

Symptoms of congestive heart failure occur most commonly during exercise, but cardiac performance is usually quantitated at rest. The relation between exercise capacity and measurements of cardiac performance at rest is little known. Treadmill exercise was performed in 21 patients with heart failure due to cardiomyopathy. Exercise duration averaged 9.1 ± 0.7 (standard error of the mean) minutes (normal value 12 or more minutes) and did not correlate with resting ejection fraction of 26.4 ± 2.7 percent ($r = -0.06$). Left ventricular diastolic dimension of 6.6 ± 0.2 cm, mean velocity of circumferential fiber shortening and ratio of preejection period to left ventricular ejection time did not correlate with treadmill time ($r = -0.03$). Repeat studies after treatment of heart failure also failed to show correlations between changes in exercise capacity and changes in left ventricular performance at rest. Thus, measures of left ventricular performance obtained at rest do not accurately reflect exercise tolerance and symptomatic status of patients with congestive heart failure.

Patients with congestive heart failure are usually symptomatic during exertion, and it is common clinical practice to estimate their functional capacity and symptomatic status in terms of exercise tolerance.[1] Severity of heart failure is also frequently assessed from measurements of cardiovascular performance obtained at rest, but the relation of these measurements to functional capacity has not been well defined in patients with heart failure. We[2] recently reported that hemodynamic measurements at rest, including left ventricular filling pressure and cardiac output, do not correlate with exercise capacity in patients with chronic left ventricular failure. Because abnormal left ventricular function is thought to be a major cause of impaired exercise capacity in patients with heart failure, and because systemic hemodynamics are affected by factors other than left ventricular performance, it is possible that measures that more closely reflect left ventricular performance would be more predictive of exercise capacity.[3] We therefore performed this study to determine the relations between noninvasively measured indexes of left ventricular function and exercise capacity in ambulatory patients with chronic left ventricular failure.

Methods

Patients: The study group consisted of 21 ambulatory patients aged 38 to 72 years with chronic left ventricular failure who were undergoing baseline evaluation before entry into therapeutic trials with vasodilator drugs. The diagnosis of left ventricular failure was based on a history of exercise intolerance due to dyspnea or fatigue and clinical or radiographic evidence of pulmonary congestion. In addition, patients had to have one of the following: (1) increased heart size by radiologic criteria (cardiothoracic ratio greater than 55 percent); (2) left ventricular diastolic diameter greater than 5.0 cm by echocardiographic examination; and (3) left ventricular ejection fraction below 45 percent by radionuclide or contrast angiography. Symptoms of heart failure must have been present for at least 3 months during treatment with digitalis and diuretic agents.

From the Cardiovascular Division, University of Minnesota Medical School and the Veterans Administration Medical Center, Minneapolis, Minnesota. This study was supported in part by the Medical Research Service of the Veterans Administration, Washington, D.C. Manuscript received May 5, 1980; revised manuscript received June 24, 1980, accepted June 29, 1980.

* Current address and address for reprints: Joseph A. Franciosa, MD, Veterans Administration Medical Center, University and Woodland Avenues, Philadelphia, Pennsylvania 19104.

The etiology of heart failure was (1) ischemic cardiomyopathy (based on a history of documented acute myocardial infarction or angiographically proved coronary arterial obstructive disease); (2) primary congestive cardiomyopathy (diagnosed when no other cause of heart failure was apparent); or (3) status postvalve replacement (if prosthetic valve function was normal and symptoms of heart failure persisted). Patients were excluded for the following reasons: acute myocardial infarction within the preceding 3 months, primary valvular heart disease, primary pulmonary disease (documented by pulmonary function studies and blood gas determinations), and inability to exercise for reasons other than dyspnea or fatigue.

The clinical characteristics of the patients are shown in Table I. They consisted of 20 men and 1 woman (Case 11), and all were taking digitalis and diuretic drugs. Atrial fibrillation was present in three patients (Cases 3, 7 and 11); the remaining 18 had sinus rhythm.

Measurements of cardiac performance at rest: After giving written informed consent, all patients underwent evaluation of resting left ventricular performance. Diuretic drugs were withheld but digitalis was given on the day of study. No patient had taken a vasodilator drug for at least 2 weeks.

Cardiac output during supine rest was measured noninvasively with the carbon dioxide rebreathing method, an indirect Fick procedure. We have previously validated this noninvasive method in patients with congestive heart failure and found that the results correlated closely with those obtained with the dye-dilution technique.[4,5] Heart rate was measured from a standard electrocardiogram and blood pressure with use of the cuff method.

M mode echocardiograms were obtained with the patient in the supine or left semilateral position, using a Smith-Kline Ekoline Ultrasonoscope and a 2.25 megahertz transducer. The echocardiograms were recorded on a Honeywell direct-writing recorder. Left ventricular end-diastolic and end-systolic dimensions were measured below the tips of the mitral valve leaflets. End-diastole was taken at the peak of the R wave of the electrocardiogram, and end-systole was taken at the shortest distance between septal and posterior walls. External carotid pulse tracings were recorded simultaneously with the echocardiogram, and left ventricular ejection time was measured from the beginning of the upstroke of the carotid pulse to the dicrotic notch. Mean velocity of circumferential fiber shortening was calculated in circumferences per second as the difference between left ventricular end-diastolic and end-systolic dimensions (in cm) divided by the product of left ventricular end-diastolic dimension (in cm) and left ventricular ejection time (in ms).

Systolic time intervals were measured from simultaneous recordings of the external carotid pulse, electrocardiogram and phonocardiogram. The carotid pulse wave was recorded from a brass funnel connected to a Bell and Howell physiologic pressure transducer. The phonocardiogram was recorded from a microphone positioned to record a clear aortic component of the second heart sound (S_2). Electromechanical systole was measured from the onset of the QRS complex to the first high frequency deflection of S_2 ($Q\text{-}S_2$), and left ventricular ejection time (LVET) was measured as described earlier. The preejection period (PEP) was taken as the difference between $Q\text{-}S_2$ and left ventricular ejection time in ms. The ratio PEP/LVET was calculated without correcting for heart rate, which has little effect on this ratio.[6]

Left ventricular ejection fraction was measured with radionuclide imaging techniques using a gated method.[7] The patient's red cells are labeled in vivo with technetium-99m pertechnetate 15 minutes before imaging.[8] Twenty-eight frame multigated studies are obtained over a 5 minute acquisition time and, after background correction, left ventricular ejection fraction is calculated in percent as the difference between end-diastolic and end-systolic counts divided by end-diastolic counts.

Treadmill exercise testing: On completion of all resting measurements, patients underwent upright treadmill exercise testing to a symptom-limited maximum of dyspnea or fatigue using a modified Naughton protocol,[9] which was carried out in the following 2 minute stages: I = 1 miles/hour, 0 percent grade; II = 2 miles/hour, 0 percent grade; III = 2 miles/hour, 3.5 percent grade; IV = 2 miles/hour, 7 percent grade; V = 2 miles/hour, 10.5 percent grade; VI = 3 miles/hour, 7.5 percent grade; VII = 3 miles/hour, 10 percent grade; VIII = 3 miles/hour, 12.5 percent grade; IX = 3 miles/hour, 15 percent grade; and X = 3.5 miles/hour, 14 percent grade. In 14 patients, expired air was continuously collected during exercise and passed on line through gas analyzers for determination of oxygen consumption.

Repeated studies after treatment: These studies at rest and during exercise were repeated in 13 patients 5 weeks after they had been randomly assigned, with a double blind protocol, to therapeutic trials with vasodilator drugs or placebo plus standard treatment with digitalis and diuretic drugs. Because these trials are ongoing, the patients' therapeutic regimens are still unknown. However, for purposes of the present study, the measurements obtained at 5 weeks were analyzed to determine relations between changes in indexes of left ventricular performance at rest and changes in exercise capacity.

The data were analyzed using standard formulas for calculation of mean, standard deviation, standard errors and

coefficients of correlation. Student's paired t test was used to compare values at 5 weeks with control measurements.

Results

Resting left ventricular performance and exercise duration (Table II): Cardiac output and stroke volume could not be obtained in three patients and averaged well below normal for the group. Echocardiographically determined left ventricular end-diastolic dimension and mean velocity of circumferential fiber shortening were also abnormal in 15 patients with satisfactory determinations. The ratio of PEP/LVET was abnormally prolonged in 14 patients. Left ventricular ejection fraction was obtained in all patients and the average was markedly depressed. Exercise duration averaged only 9.1 ± 0.7 minutes in this group of patients. Normal subjects carrying out this same exercise protocol should complete at least 12 minutes.[9] In 14 patients, maximal oxygen uptake averaged 13.7 ± 1.0 ml/kg per min; in our laboratory normal subjects in this age group can achieve greater than 20 ml/kg per min.[2] All exercise tests were stopped because of either dyspnea or fatigue. No one experienced angina or ischemic electrocardiographic changes during exercise. Thus, our patients had significant exercise intolerance accompanied by marked abnormalities of left ventricular performance at rest consistent with significant left ventricular failure.

Correlations between data at rest and exercise performance: The data were analyzed for correlations between indexes of left ventricular performance at rest and exercise duration. Systemic hemodynamic variables did not correlate with exercise duration (r = −0.10 for cardiac output, 0.07 for stroke volume, −0.21 for mean arterial pressure and 0.17 for systemic vascular resistance). Echocardiographically determined left ventricular diastolic dimension did not correlate with exercise duration, and the patient with the smallest dimension had the second shortest exercise duration (Fig. 1). Neither mean velocity of circumferential fiber shortening (Fig. 2) nor the PEP/LVET ratio (Fig. 3) correlated with exercise duration. Left ventricular ejection fraction also failed to correlate with exercise duration (Fig. 4), and the patient with the highest ejection fraction of 63 percent (Patient 11) had one of the shortest exercise durations (4.7 minutes) and the patient with the greatest exercise duration of 17 minutes (Patient 20) had a resting ejection fraction of only 25 percent. Ejection fraction was obtained in the three patients with atrial fibrillation because their ventricular rates were well controlled with only minimal irregularity.

Correlations in repeated studies: The relations between changes in indexes of resting left ventricular performance and changes in exercise capacity were examined in the 13 patients who underwent the same studies after 5 weeks of treatment (Table III). In this subgroup, exercise duration increased significantly by 1.5 ± 0.5 minutes ($p < 0.01$), whereas resting hemodynamic values, echocardiographic variables, PEP/LVET ratio and ejection fraction were not significantly changed after 5 weeks. Likewise, there was no significant correlation between changes in exercise duration and changes in resting indexes of left ventricular performance.

Discussion

Correlation of clinical symptoms, exercise capacity and left ventricular performance: In the absence of impaired ventilatory function, skeletal muscle abnormalities or inability of blood to carry adequate amounts of oxygen, cardiovascular performance becomes the major determinant of exercise capacity. Therefore, patients with heart failure are usually limited in their capacity to exercise, presumably because impaired left ventricular performance has led to an excessive increase in pulmonary capillary pressure and premature dyspnea or inadequate cardiac output and early muscle fatigue.[3,10] It is common clinical practice to estimate the severity of heart failure symptoms by relating them to their precipitating physical activities.[1] However, when such clinical classifications are compared with actual quantitation of exercise capacity in patients with heart failure, the correlation is not very good.[2,9] Measurements of cardiovascular performance

CO = cardiac output; EF = left ventricular ejection fraction; n = number of studies; NS = not significant; PEP/LVET = ratio of preejection period to left ventricular ejection time; SEM = standard error of the mean; SV = stroke volume; VCF = velocity of circumferential fiber shortening.

at rest are also frequently used to assess the severity of heart failure. Although these measurements often provide useful information to help guide short-term therapeutic interventions and may also be of prognostic value in predicting length of survival, their relation to symptomatic severity and functional capacity is not well established.[11] Recent therapeutic trials[12,13] have shown that acute improvement in left ventricular performance is not associated with increased exercise tolerance in patients with left ventricular failure. Conversely, other studies[14,15] in similar patients have demonstrated improved exercise capacity during long-term therapeutic interventions that were not associated with significant changes in indexes of left ventricular performance at rest.

We recently reported that resting hemodynamic measurements, including left ventricular filling pressure and cardiac output, although markedly abnormal in patients with impaired exercise tolerance and heart failure, did not separate groups with varying severity of exercise intolerance. We found no correlations between resting left ventricular filling pressure, cardiac output, stroke volume or systemic vascular resistance and maximal oxygen uptake. However, these hemodynamic measurements are determined by factors other than left ventricular function. Systemic vascular resistance through its effects on impedance is a major determinant of output of the failing ventricle and, because resistance decreases greatly during exercise, cardiac output at rest may not reflect what happens during exercise.[3,16] Left ventricular filling pressure, besides being influenced by diastolic characteristics of the left ventricle, is also a function of intravascular volume and left ventricular outflow resistance.[17]

Left ventricular performance at rest for predicting exercise capacity: Thus, the present study was intended to assess the relation of exercise capacity to more direct measures of left ventricular function. Although assessment of myocardial contractility of the intact heart is notoriously difficult, the noninvasive measures used in this study are all thought to reflect left ventricular performance to some degree. Left ventricular diastolic dimension and mean velocity of circumferential fiber shortening are both believed to be indicators of contractile function.[18] Of course, use of these echocardiographic measurements in the present study involving predominantly patients with ischemic heart disease may be questioned because of the spatial limitations of M mode echocardiography and geometric asymmetry of the left ventricle in such patients.[19] Left ventricular ejection fraction is a widely used measure of contractile function and, when measured with blood pool imaging methods, is a reliable index and not affected by ventricular geometry.[20–22] Likewise, systolic time intervals, especially the PEP/LVET ratio, are thought to reflect contractility independent of ventricular geometry and, in some studies, PEP/LVET has correlated closely with ejection fraction.[6] All of these ejection phase indexes were found to be markedly abnormal and consistent with moderately severe left ventricular dysfunction and failure in the present study. Our patients also had very limited exercise capacity, but within this group of incapacitated patients, we found no correlations between exercise capacity and the measures of left ventricular performance at rest. These results are similar to those of Benge et al.[23] who also found no correlation between ejection fraction at rest and exercise capacity in cardiac patients.

Our observations were also repeated after treatment of heart failure and, although exercise duration was increased, measures of ventricular performance at rest were unchanged. Furthermore, there were no correlations between changes in resting ejection phase indexes and changes in exercise capacity. Thus, knowledge of resting indexes of left ventricular performance is not predictive of exercise capacity in patients with chronic left ventricular failure; also, changes in ventricular performance at rest do not appear to be useful for following changes in functional capacity of such patients. In fact, Lee et al.[24] recently noted improved exercise capacity without changes in left ventricular function after training in patients with coronary artery disease and a low ejection fraction.

These results should not be too surprising because exercise itself may produce marked changes in left ventricular performance. Heart rate increases strikingly and is the major contributor to increasing cardiac output. Contractility may increase as a result of increased preload or catecholamine release, or both. Preload and ejection fraction are variably altered, and impedance would be expected to decrease as a result of decreased systemic vascular resistance, which may, however, be offset by the increase in systolic blood pressure and the vasoconstriction in nonexercising vascular beds.[3,25] The net effects of the interplay of all these factors can not be predicted from knowledge of their resting state. It is quite likely that hemodynamic responses and changes in ventricular performance during exercise are major determinants of exercise capacity in patients with heart failure.[26]

Possible limitations of study: This study is weakened by a lack of similar data in normal subjects or subjects with mild cardiac disease, and our results are applicable only to patients with limited exercise capacity and impaired cardiac function. Furthermore, we have studied only patients who were limited by symptoms of heart failure and excluded those limited by myocardial ischemia. The exercise protocol employed is also subject to criticism. Patients were not previously familiarized with the exercise testing procedure, but we have previously observed no significant variation between results obtained from successive tests at 90 minute intervals in patients with heart failure.[2,12–24] The use of 2 minute stages might also be questioned, but we have previously reported that maximal oxygen uptake achieved with the present protocol is the same as that achieved during a bicycle exercise test employing 4 minute stages in the same patients.[2] The maximal oxygen uptake occurs at a time when the ventilatory exchange ratio is elevated, indicating onset of anaerobic metabolism and achievement of maximal or very near maximal stress.[2,12–14]

Implications: Our study confirms previous observations that hemodynamic measurements at rest are not predictive of exercise capacity in patients with left ventricular failure. It also establishes that more direct measures of left ventricular performance likewise fail to correlate with exercise capacity in these patients. Therefore, exercise testing is preferred in order to assess functional capacity of patients with heart failure. Evaluation of the many new interventions for heart failure should not focus solely on hemodynamic effects or changes in ventricular performance as the primary goal, but should include exercise testing to monitor patient progress and judge therapeutic efficacy. Although ejection phase indexes of myocardial contractility are of prognostic value,[22,27] exercise testing may be preferable in evaluating quality of life, which could be favorably altered without necessarily improving cardiac performance or longevity.

Systolic and Diastolic Properties of the Human Left Ventricle During Valve Replacement for Chronic Mitral Regurgitation

CALVIN Y.H. WONG, MD*
HENRY M. SPOTNITZ, MD, FACC†

New York, New York

M mode and two dimensional echocardiography were combined with pressure-flow data to analyze systolic mechanics and diastolic compliance in nine patients during valve replacement for chronic mitral regurgitation. Both M mode (six patients) and two dimensional (four patients) echographic analyses revealed large decreases in early postoperative shortening fraction (-24 ± 17 [standard deviation] percent M mode study, $p < 0.01$; -30 ± 12 percent two dimensional study, $p < 0.02$), which were significantly different from small changes observed in control subjects (M mode study, $+7 \pm 10$ percent, 25 subjects and two dimensional study, -7 ± 14 percent, 8 subjects). Additional data suggest that left ventricular compliance is increased in chronic mitral regurgitation and that elimination of the low impedance left atrial pathway by valve replacement is associated with a significant increase in wall stress (five patients, $p < 0.02$) that appears to be responsible for the decreased ejection fraction postoperatively. Analysis of hemodynamic variables other than ejection fraction and rate of circumferential shortening revealed no difference between five postoperative patients with chronic mitral regurgitation and five with coronary artery disease. These results in human subjects confirm predictions from studies in animal models and suggest that unique properties of chronic mitral regurgitation demand special attention when patients with this condition are being evaluated for surgery.

The clinical course of chronic mitral regurgitation is typically one of slow progression over many years with late development of symptoms.[1–5] Indications for valve replacement are traditionally based on the development of these symptoms.[6] Despite the apparent slow progression and often comparatively favorable medical assessment of hemodynamic status, patients undergoing valve replacement for chronic mitral regurgitation have higher postoperative morbidity and mortality rates with greater depression of hemodynamic performance than have patients undergoing surgery for mitral stenosis or most other adult cardiac lesions.[6–16] This depression of ventricular performance in chronic mitral regurgitation is manifested as depressed postoperative ejection fraction and has been shown to persist on long-term follow-up study.[8,17–18]

Animal models of acute and chronic mitral regurgitation have demonstrated an increase in afterload after reversal of the lesion.[4,19–20] This finding suggests that valve replacement for chronic mitral regurgitation exposes pathologic depression of left ventricular performance that is not readily apparent preoperatively and that leads to an adverse postoperative outcome.[19] The direct effect of valve replacement on left ventricular function and systolic mechanics in patients with chronic mitral regurgitation has not been demonstrated. The purpose of this study, therefore, is to utilize intraoperative measurements of hemodynamic function,

ventricular compliance and systolic mechanics to demonstrate properties unique to chronic mitral regurgitation that would serve to identify these patients as a distinct group requiring special attention.

Methods

Patients: Left ventricular properties were studied intraoperatively at the time of cardiac surgery in 9 patients with predominant chronic mitral regurgitation and compared with findings in a general population of 33 patients undergoing open heart surgery for a condition other than chronic mitral regurgitation. Measurements were obtained intraoperatively before and after completion of cardiopulmonary bypass. The withdrawal and infusion of blood that normally accompany the use of the heart-lung machine provided a natural physiologic laboratory to complete our studies. Informed consent was obtained before surgery. There were no study-related complications.

Pressure-flow data: To obtain pressure and flow data, a Millar Mikro-tip velocity/pressure transducer catheter (VPC-663A, Millar Instruments Inc., Houston, Texas) was inserted through an injection site in the ascending aorta, and the pressure sensor was positioned in the left ventricular cavity. A high frequency differentiator was used to provide the first derivative of left ventricular pressure (dP/dt) (Cardiac Contractility Computer SB-20B, Crane Bio-Medical Instruments, Inc., Elmont, New York). Flow data for systolic mechanics were provided by an electromagnetic flow velocity probe, 2 cm proximal to the catheter tip, positioned just above the aortic valve. A Swan-Ganz thermodilution catheter (Edwards Laboratories, Santa Ana, California) was placed in the main pulmonary artery. Pressure-flow data for left ventricular mechanics were obtained simultaneously with thermodilution determinations of cardiac output to calibrate the flow-velocity probe. Radial arterial pressures were recorded using a percutaneous Teflon® catheter and fluid-coupled pressure transducer. The opening and closing of the aortic valve could be determined from simultaneous left ventricular and radial arterial pressures after correction for the time delay in the radial arterial pressure (Fig. 1).

M mode echocardiography: A 3.5 megahertz low profile M mode echographic transducer (Aerotech Laboratories, Lewistown, Pennsylvania) imbedded in a Silastic® disc for stability was inserted into the posterior pericardium in a retrocardiac position. This technique did not cause interference with surgery. Echographic data (ECT Echocardiotrace, Metrix, Inc., Denver, Colorado) and pressure-flow data for left ventricular mechanics were recorded with an optical oscillograph equipped to record M mode echocardiograms and standard analog data signals (1858 CRT Visicorder, Honeywell, Inc., Denver, Colorado). This method has previously been described.[21,22] Left ventricular end-diastolic and end-systolic diameters were obtained from the M mode echocardiogram. The end-diastolic diameter was measured from the top of the R wave of the simultaneously occurring electrocardiogram. The end-systolic diameter was measured at the point where the opposing ventricular walls most closely approximated each other.

Two dimensional echocardiography: In selected patients, evaluation of left ventricular performance was based on changes in the short axis cross section measured with two dimensional phased array echocardiography. A gas-sterilized 3.5 megahertz two dimensional echographic transducer (Varian V-3000 Electronic Phased Array Ultrasonograph, Varian, Palo Alto, California) was placed against the anterior surface of the right ventricle to obtain cross sections at the level of the tip of the mitral valve leaflets. Quantitative analysis of the video images obtained was performed using the V-3000 Microprocessor Controlled Light Pen. The end-diastolic area was determined with planimetry from the video image synchronous with the peak of the R wave of the electrocardiogram. The end-systolic area was chosen as the smallest area determined with planimetry during systole.

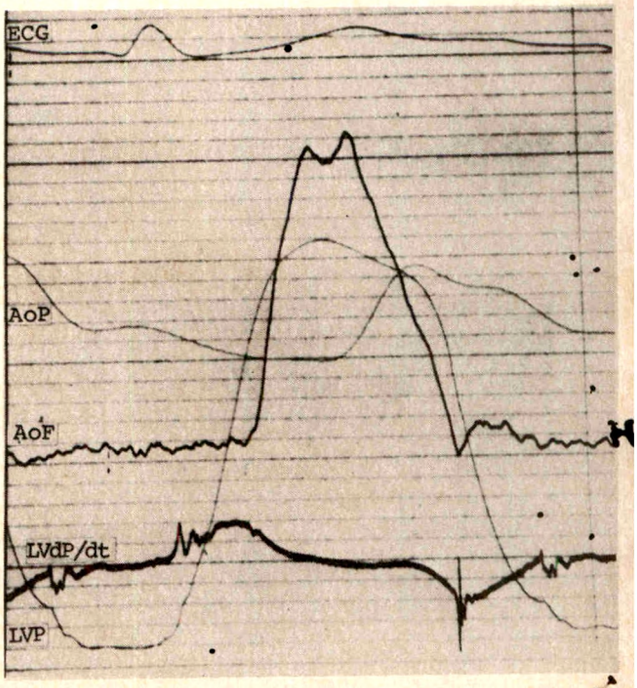

FIGURE 1. Patient 4. Representative intraoperative data recording after cardiopulmonary bypass and valve replacement for chronic mitral regurgitation. Aortic pressure (AoP) is measured from a radial arterial catheter and contains an appropriate time delay in recording of the tracing. AoF = aortic flow; ECG = electrocardiogram; LVdP/dt = first derivative of left ventricular pressure; LVP = left ventricular pressure.

Protocol for data acquisition: All studies were performed after aortic cannulation for cardiopulmonary bypass as a safeguard against hypotension or arrhythmias during the studies. However, no such problems were observed. Catheters were inserted after heparinization and removed before administration of protamine. The order of instrumentation when all studies were performed was catheter insertion, two dimensional echocardiography and M mode echocardiography. Studies were conducted in reverse order after cardiopulmonary bypass. The presence of pericardial adhesions was a contraindication to M mode echocardiography from the retrocardiac position. The presence of valve vegetations was a contraindication to catheter placement. Two dimensional echocardiographic equipment was not available for early studies.

Of the total of nine patients with chronic mitral regurgitation, five had complete studies of left ventricular mechanics, four had satisfactory studies of left ventricular compliance (pressure-diameter data), six had M mode studies of shortening fraction, and four had two dimensional echographic

studies of ejection fraction. Similar constraints applied to the control group.

Angiographic data: Cardiac catheterization was performed as part of the preoperative evaluation in all patients. End-diastolic volume, ejection fraction and left ventricular mass were obtained from the contrast cineventriculogram taken in the standard right anterior oblique view (Table I). Quantitative analysis was based on the single plane area-length method.[23–25] Comparison of left ventricular end-diastolic pressure during angiography with observations in the open chest was facilitated by assuming an intrapleural pressure of −7 mm Hg during angiography and adding this value to left ventricular end-diastolic pressure to obtain effective transmural pressure.

Calculations

Compliance curves: Left ventricular end-diastolic pressure was plotted against left ventricular end-diastolic diameter as a measure of diastolic compliance.[21,22,26] Pressure was obtained directly from the indwelling micromanometer, and end-diastolic diameter (EDD) was obtained from the retrocardiac M mode echocardiogram. Echocardiographically determined volume ($V = EDD^3$)[27–29] intraoperatively was related to the preoperative angiographically determined volumes (single plane area-length method) with use of a nomogram that has a correlation coefficient of 0.82 in our laboratory (Fig. 2). Data were analyzed by an exponential curve fitting to the relation: $EDD = ae^{bEDD}$ where the constants a and b were averaged for statistical comparisons.

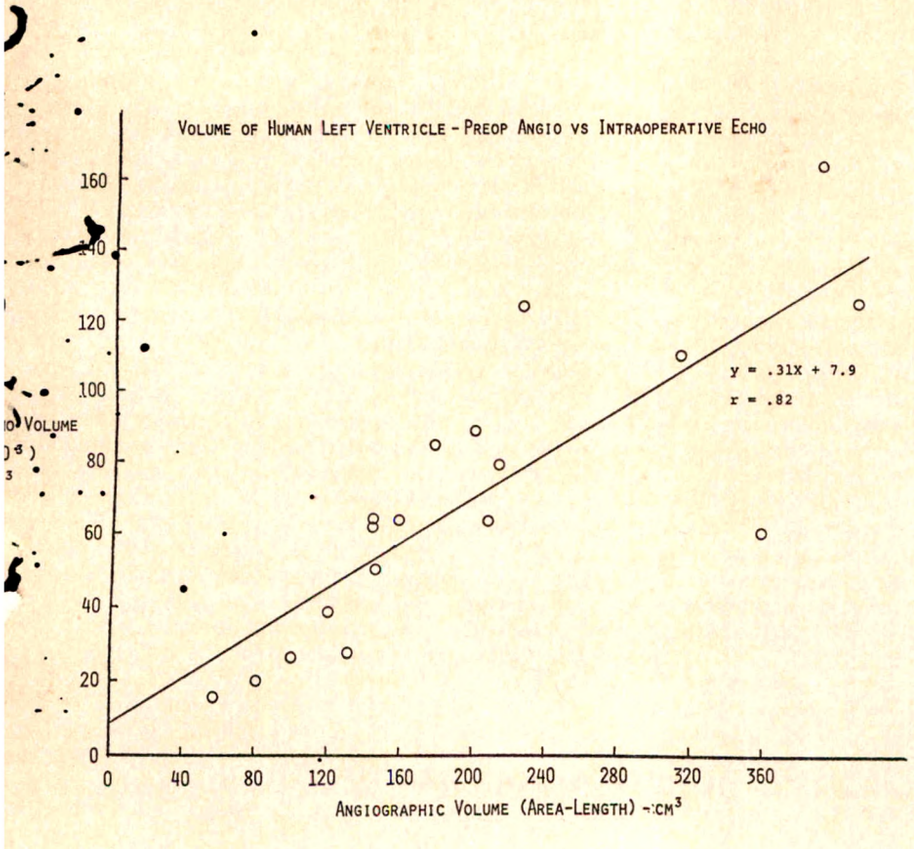

FIGURE 2. Linear regression for the relation of angiographically determined left ventricular volume to intraoperative measurements (D^3) by M mode echocardiography. The regression formula is illustrated.

Ejection fraction: Measurements of left ventricular dimensions with M mode (left ventricular diameter) and two dimensional (left ventricular cross-sectional area) echocardiography were treated similarly to obtain fractional changes during systole. For M mode data, shortening fraction (SF) was defined as SF = (EDD − ESD)/EDD, where EDD and ESD are end-diastolic and end-systolic diameter, respectively. For two dimensional short axis images, ejection fraction (EF) was defined as EF = (EDA − ESA)/EDA where EDA and ESA are end-diastolic and end-systolic area, respectively. No patients with focal wall motion abnormalities with the exception of paradoxical septal motion, were included in our two dimensional studies.

Systolic mechanics: Left ventricular pressure, aortic flow and dP/dt were measured at 20 ms intervals and entered into a PDP-11/70 computer for calculation of variables of systolic mechanics using a changing volume spherical model.[30] Left ventricular volume (V) is given by V = end-diastolic volume − SV, where end-diastolic volume is obtained from end-diastolic diameter and the nomogram, and SV is instantaneous stroke volume from the flow-velocity curve, calibrated by simultaneous thermodilution stroke volume. Instantaneous chamber radius (Ri) is then given by $Ri = (0.239\ V)^{1/3}$. Similarly, external radius (Ro) of the spherical "ventricle" is given by $Ro = (0.239[V + M])^{1/3}$, where M = left ventricular mass, determined angiographically. Left ventricular wall stress is calculated as wall stress = $\pi PRi^2/(Ro^2 - Ri^2)$ where P = left ventricular pressure, Ri = internal radius and Ro = external radius.[30]

The calculation of the velocity of contractile element shortening (*Vce*) is based on the two component model for cardiac muscle where a contractile element is linked in series to a series elastic element.[31,32] Vce is equal to the sum of the velocity of circumferential shortening (Vcf) and the velocity of the series elastic element elongation (Vse). It has been shown that Vcf (cm/s) = Q (cm^3/s)/2RoRi (cm^2), where Q = instantaneous flow out of the ventricle.[20,33] The velocity of series elastic element elongation is determined from the equation Vse = (dT/dt)/KT where T = wall tension (g/cm^2) and KT = the modulus of elasticity of the series elastic component of muscle.[30,32] The normalized value for K used in this study is 28.6, a value based on observations on the isolated heart muscle.[32,34]

Ventricular volume during mitral regurgitation required estimation of the regurgitant fraction in addition to the stroke volume directly recorded by the aortic flow probe. To solve this problem, total ejection volume was determined by subtracting the end-systolic from the end-diastolic volume. Both volumes were obtained from M mode measurements of end-systolic and end-diastolic diameters and related to angiographically determined volumes through the nomogram discussed earlier (Table I). The measured aortic flow was then calibrated by setting the integrated stroke volume equal to the total ejection volume, assuming equal rates of ejection into the aorta and left atrium. Instantaneous volume was obtained by subtracting the newly calibrated aortic flow (calibrated to equal ejection volume) from the end-diastolic volume.

Statistical tests: Simple statistics were done with a programmed hand calculator (S-61, Commodore). Mean values for simple hemodynamic variables in different populations were compared with unpaired *t* tests (see Fig. 4 and 5, Table III). Changes within a single population were compared by paired *t* test (Table II). Significance of differences between exponentials fitted to compliance curves was tested with an unpaired *t* test applied to the base and exponential constants.

Integral of Systolic Wall Stress (g/cm^2) After Mitral Valve Replacement in Five Patients

Case	Preoperative	Postoperative
1	18.9	31.1
2	29.0	30.3
3	19.9	31.8
4	28.8	43.4
5	33.0	43.4
Mean*	25.9 ± 6.2	36.0 ± 6.8

* $p < 0.02$, paired *t* test, preoperatively versus postoperatively.

Results

Diastolic pressure-diameter relations: Average end-diastolic pressure-diameter curves for four patients with chronic mitral regurgitation and three patients with mitral stenosis are illustrated in Figure 3. The exponential equation derived for mitral stenosis (line B) is: $EDP = (0.09 \pm 0.02)e^{(1.45\pm0.17)\ EDD}$, where EDP = left ventricular end-diastolic pressure and EDD = left ventricular end-diastolic diameter. The exponential equation derived for chronic mitral regurgitation (line A) is: $EDP = (0.52 \pm 0.35)e^{(0.72\pm0.18)EDD}$. The curve representing chronic mitral regurgitation is shifted to the right and the slope is decreased at any given end-diastolic pressure compared with the pressure curve representing mitral stenosis. However, observed differences in the base and exponential constants of the derived regressions are not statistically significant.

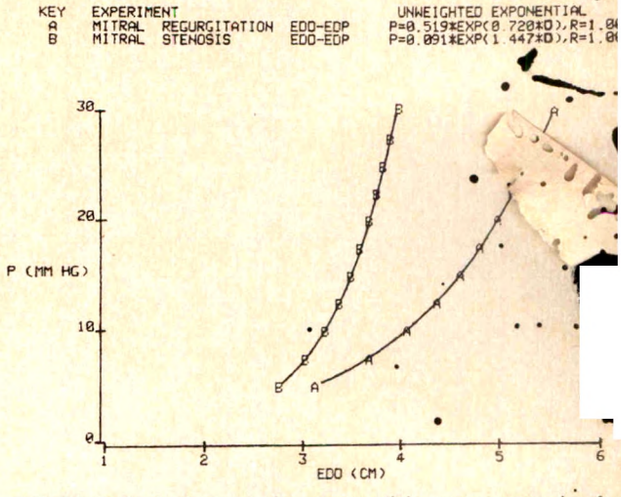

FIGURE 3. Derived composite exponential curves comparing four patients with chronic mitral regurgitation (A) and three patients with mitral stenosis (B). P = pressure. Chronic mitral regurgitation is associated with an increase in left ventricular compliance characterized by a shift of the curve to the right and by decreased slope at any given left ventricular end-diastolic pressure. EDD = end-diastolic diameter; EDP = end-diastolic pressure.

Shortening fraction: Preoperative and postoperative M mode shortening fractions for 6 patients with chronic mitral regurgitation and 25 control patients are illustrated in Figure 4. The control group consisted of 11 patients undergoing coronary revascularization, 5 having aortic valve replacement, 5 having mitral valve replacement for mitral stenosis, 3 undergoing closure of secundum type atrial septal defect and 1 patient undergoing correction of congenital pulmonary stenosis. The control group showed an average 7 ± 10 percent increase in postoperative M mode shortening fraction from 27 ± 15 to 34 ± 15 percent ($p < 0.01$, paired t test). The patients with chronic mitral regurgitation showed a 24 ± 17 percent decrease in postoperative M mode shortening fraction from 37 ± 12 to 13 ± 10 percent ($p < 0.01$, paired t test). The decrease in postoperative M mode shortening fraction seen in the group with chronic mitral regurgitation was statistically significant ($p < 0.001$, unpaired t test) compared with the increase in the postoperative M mode shortening fraction seen among the control group.

Preoperative and postoperative two dimensional "ejection fraction" (Fig. 5) were compared in four patients with chronic mitral regurgitation and eight control subjects, including three patients undergoing aortic valve replacement, three undergoing mitral valve replacement for mitral stenosis, one patient undergoing coronary revascularization and one undergoing triple valve replacement for bacterial endocarditis. The control subjects showed an average 7 ± 14 percent decrease

VCe (cm/s)	18 ± 5	15 ± 2
Peak dP/dt (mm Hg/s)	927 ± 182	1102 ± 525
Time to peak (ms)	72 ± 27	88 ± 36

* $p < 0.02$, unpaired t test, mitral regurgitation versus coronary artery disease.

Ao flow = aortic flow; circ = circumference; dp/dt = first derivative of left ventricular pressure; EDV = end-diastolic volume; LVEDP = left ventricular end-diastolic pressure; LVP = left ventricular pressure; PVSW = pressure-volume stroke work; r/h = radius/wall thickness; TTI = tension-time index; VCe = velocity of contractile element shortening; VCf = velocity of fiber shortening.

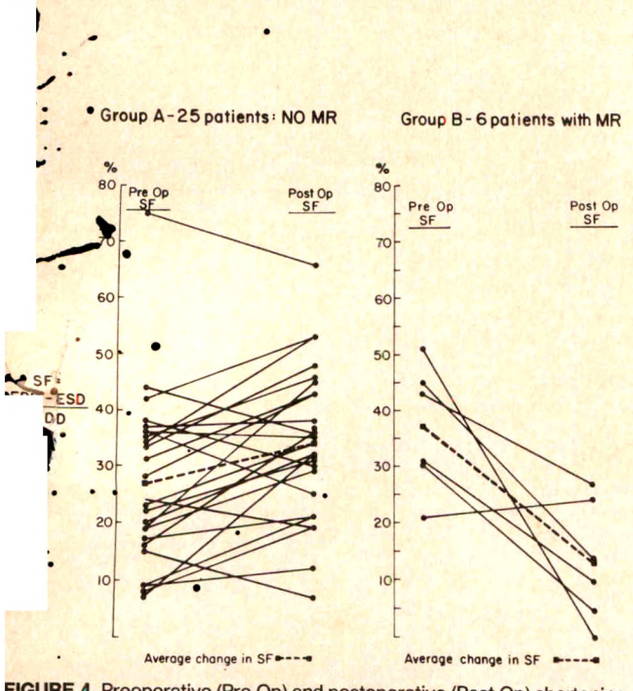

FIGURE 4. Preoperative (Pre Op) and postoperative (Post Op) shortening fractions (SF) compared in 25 patients with no mitral regurgitation (MR) (Group A) and 6 patients with chronic mitral regurgitation (Group B). The **dashed lines** represent the average change in SF. Shortening fraction increases significantly in Group A and decreases significantly in Group B ($p < 0.001$, unpaired t test compared with the rise in Group A).

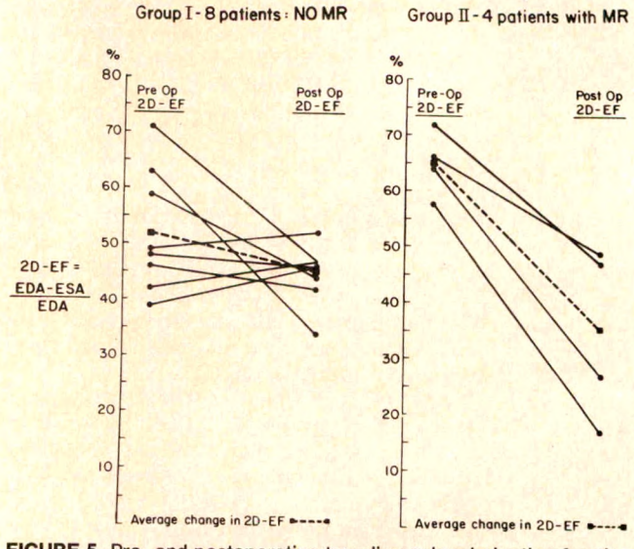

FIGURE 5. Pre- and postoperative two dimensional ejection fraction (2D-EF) compared between Group I consisting of eight patients with no mitral regurgitation and Group II consisting of four patients undergoing valve replacement for chronic mitral regurgitation. The **dashed lines** represent the average change in 2D-EF. A small decrease in postoperative shortening fraction in Group I is not statistically significant. Shortening fraction in Group II is significantly decreased postoperatively ($p < 0.02$, unpaired t test compared with that in Group I). EDA = the planimetered end-diastolic area; ESA = the planimetered end-systolic area.

in postoperative two dimensional "ejection fraction" from 52 ± 11 to 45 ± 6 percent, which was not statistically significant ($p < 0.10$, paired t test). The patients with chronic mitral regurgitation showed an average 30 ± 12 percent decrease in postoperative two dimensional "ejection fraction" from 65 ± 6 to 35 ± 16 percent ($p < 0.02$, paired t test). The greater decrease in postoperative two dimensional "ejection fraction" in the group with chronic mitral regurgitation compared with that in the control group was statistically significant ($p < 0.02$, unpaired t test).

Left ventricular mechanics: The time course of selected variables of left ventricular performance in chronic mitral regurgitation immediately before and after valve replacement is presented in Figure 6. Illustrated are left ventricular pressure, radius, wall thickness and wall stress at equivalent left ventricular end-diastolic pressures. Postoperatively, there is an increase in systolic pressure and wall stress during the latter part of systole. Systolic shortening is decreased, and less change in radius is apparent. There is a decrease in the extent of wall thickening. Differences are maximal late in systole, reflecting decreased changes in left ventricular volume with systole after correction of chronic mitral regurgitation.

The time course of preoperative and postoperative wall stress in the five patients with chronic mitral regurgitation studied is illustrated in Figure 7. The integrals of these wall stress curves (Table II) are increased in all five patients after valve replacement. The average increase from 25.9 ± 6.2 to 36.0 ± 0.8 g/cm^2 is statistically significant ($p < 0.02$, paired t test).

Comparison with coronary disease: Table III compares average postoperative left ventricular mechanics in five patients with chronic mitral regurgitation and five patients undergoing revascularization for coronary artery disease. Left ventricular volume and mass were significantly increased in the patients with chronic mitral regurgitation ($p < 0.02$) and velocity of circumferential fiber shortening at peak wall stress was significantly decreased in this group. Other calculated variables of left ventricular performance were not sig-

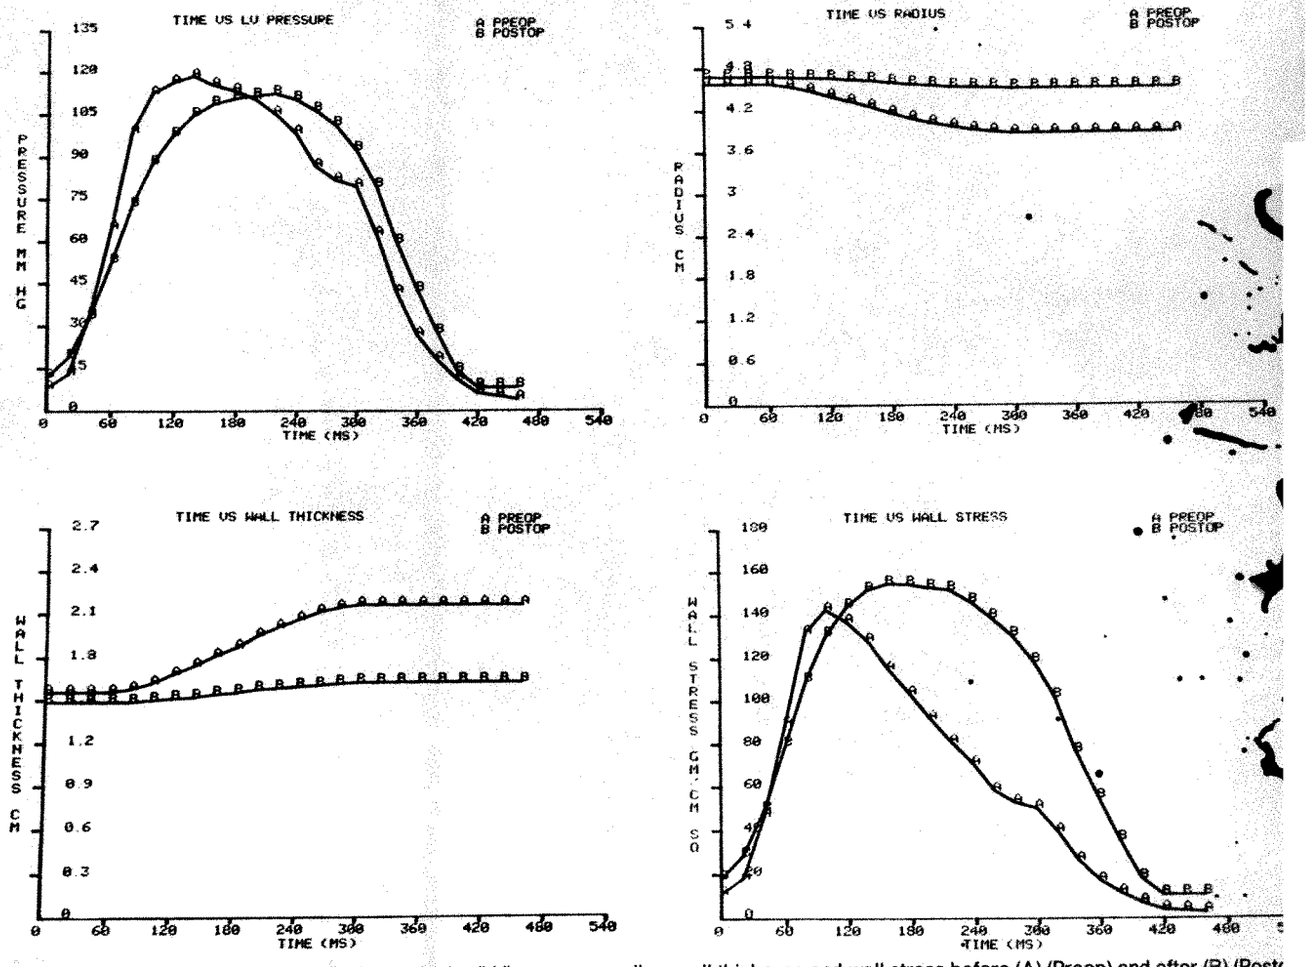

FIGURE 6. Patient 4. Time course of left ventricular (LV) pressure, radius, wall thickness and wall stress before (A) (Preop) and after (B) (Postop) valve replacement for chronic mitral regurgitation.

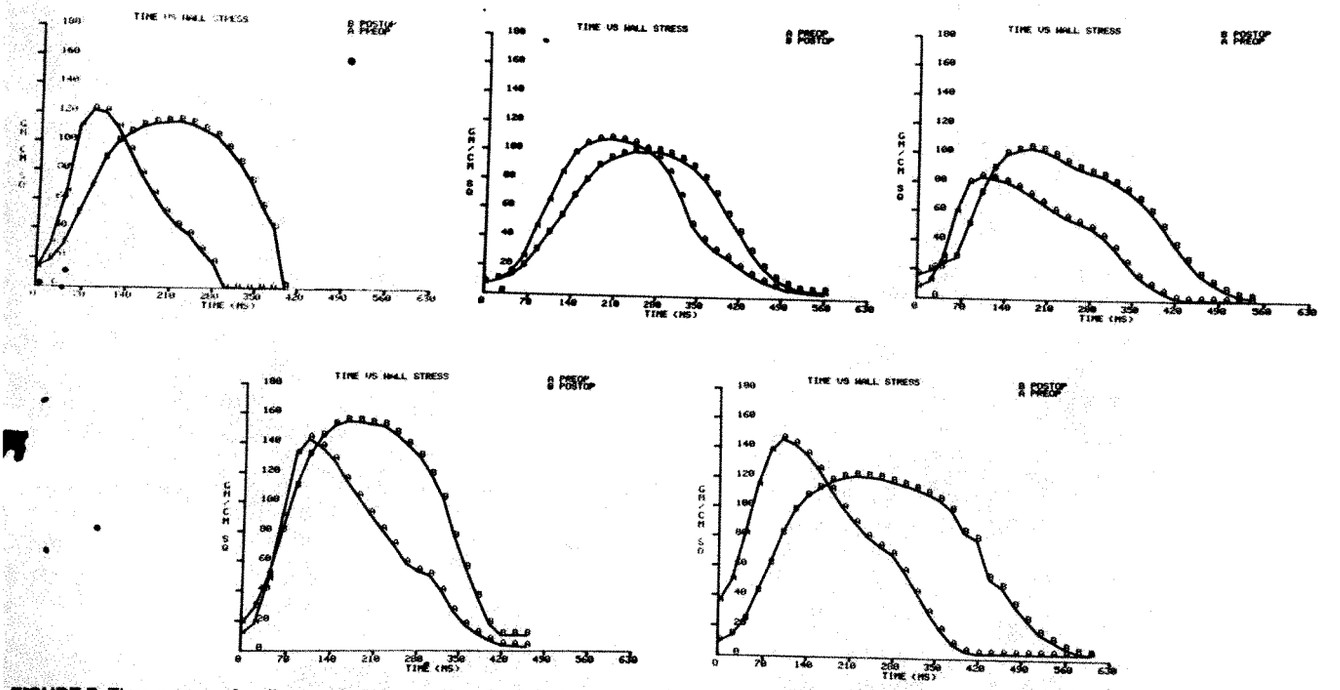

FIGURE 7. Time course of wall stress in five patients with chronic mitral regurgitation preoperatively (A) and postoperatively (B) after valve replacement. A general pattern of an accelerating decrease in systolic wall stress preoperatively and of a sustained increase in systolic wall stress after valve replacement is apparent.

nificantly different. The time course of postoperative wall stress in a representative patient with chronic mitral regurgitation and one with coronary artery disease was also similar (Fig. 8).

Discussion

Our results confirm in human beings the acute occurrence of decreased left ventricular ejection after mitral valve replacement for chronic mitral regurgitation. The data demonstrate statistically significant decreases in both M mode shortening fraction and short axis cross-sectional area reduction during systole. These changes are unique in direction and magnitude to chronic mitral regurgitation, with the notable exception of some patients in our control group who underwent acute correction of aortic insufficiency. Our results are thus consistent with depression of left ventricular function in chronic mitral regurgitation, which is not readily apparent until after valve replacement. Laboratory experiments[4,19,20] suggest that mitral regurgitation is characterized by decreased instantaneous impedance with a low resistance pathway for ejection from the high pressure left ventricle to the low pressure left atrium. The present results confirm this concept in patients and further corroborate that valve replacement eliminates this pathway, increasing impedance throughout systole and leading to the observed decreases in ejection fraction (Fig. 6 and 7). The extent to which preoperative ejection fraction is a useful index of postoperative performance will be dependent on the degree and chronicity of mitral regurgitation and cannot be compared directly with preoperative ejection fraction in most other forms of acquired heart disease.

Short-term postoperative morbidity and mortality are unexpectedly large in chronic mitral regurgitation, with long-term persistence of depressed left ventricular ejection fraction.[6–18] Properties unique to chronic mitral regurgitation appear to promote and maintain hemodynamic function of the left ventricle at the expense of undetected deterioration in muscle function.[4,18–19] Laboratory studies[35–39] associate chronic volume overload with progressive deterioration of ventricular contractility. To assess the degree of depression of left ventricular performance in patients with chronic regurgitation, it is desirable to examine muscle function in comparison with that of control subjects with normal left ventricular geometry, and to assess the impact of structural changes separately.

Structural Changes in Chronic Mitral Regurgitation

Structural changes of eccentric hypertrophy resulting from volume overload: These have been extensively studied and recently reviewed.[40–42] To summarize, acute volume overload results in plastic deformation of the left ventricle, which is initially reversible but ultimately results in a permanently deformed structure.[9,40–47] The result is an increase in ventricular mass,[40,44,48] a rightward shift of the pressure-volume relation (to increased volume at any given filling pressure)[9,40,44,49,50] and an alteration of the relation between sarcomere length and filling volume,

so that relatively normal myocardial sarcomere lengths are observed despite markedly increased volumes.[44] Possible mechanisms for alteration of sarcomere-volume relations include internal "slippage" of longitudinal fiber alignment or alteration of fiber angle relative to the ventricular "equator." Ventricular dilatation results in unfavorable loading conditions, because enlarged radius and diminished wall thickness increase wall stress for any given systolic pressure, according to the modified Laplace relation[30,51] and other analyses of left ventricular wall stress.[19,52,53] This unfavorable change may be partially offset by a reduced requirement for shortening, because a normal stroke volume becomes a small fraction of increased ventricular volume. In addition, increased mass in eccentric hypertrophy can normalize wall stress, if a normal relation of chamber radius to wall thickness (r/h) is preserved.[52,54] In chronic mitral regurgitation peak wall stress appears to be more important than shortening as a determinant of myocardial oxygen consumption, because oxygen consumption does not increase despite increased stroke volume.[4,55] The left ventricle tends toward a spherical or globular shape in chronic mitral regurgitation, rather than the 2:1 ellipsoid observed normally.[9] Because the mechanism of structural rearrangement in chronic mitral regurgitation is not clearly defined, the possibility exists that deposition of noncontractile material in series with contractile elements may contribute to apparent myocardial depression.

Effects on ventricular muscle function: Structural changes are reflected in the present results in parallel increases in left ventricular mass and volume (Table IV) and a tendency (not statistically significant) of the left ventricular pressure-diameter curve to shift to the right (Fig. 3). The volume to mass ratio in our patients with chronic mitral regurgitation averaged 0.87 compared with 0.66 in patients with coronary artery disease, so that a relatively normal relation of r/h was preserved (Table III). A rightward shift of the pressure-diameter curve would result in tolerable filling pressures despite a greatly increased ventricular size. The increased volume observed in chronic mitral regurgitation would otherwise elevate filling pressures beyond compatibility with life. However, increased diastolic compliance, while tending to diminish symptoms, may prolong the course of the disease beyond recovery of normal left ventricular function. The relation of pressure-diameter relations to compliance is a complex issue, because both the shape of the curve and the absolute end-diastolic pressure at any point in time are responsible for the slope of the tangent, dD/dp, which defines compliance. The difficulties of this issue are further demonstrated by animal studies[49,56] of stress versus Lagrangian strain in volume overload, which demonstrate increased left ventricular stiffness even though ventricular volumes are increased at any given filling pressure.

Systolic Mechanics in Chronic Mitral Regurgitation

Comparison of hemodynamic indexes other than ejection fraction immediately after cardiopulmonary bypass reveals little difference between patients

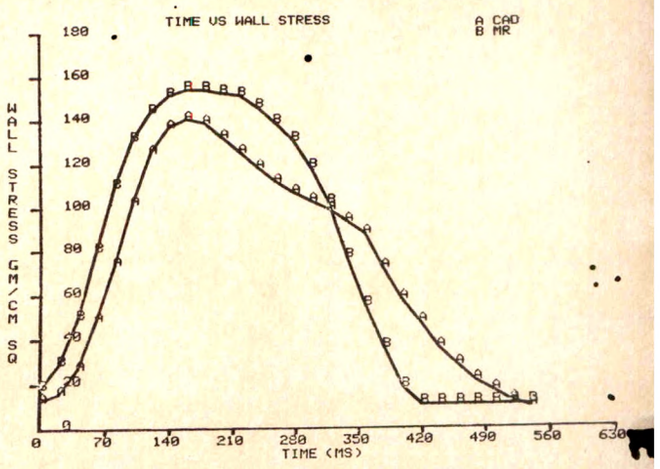

FIGURE 8. Time course of wall stress in a patient after mitral valve replacement for chronic mitral regurgitation (MR) (B) and in a patient after coronary bypass grafting for coronary artery disease (CAD) (A). Little qualitative difference is apparent despite large differences in ventricular dimensions.

undergoing valve replacement for chronic mitral regurgitation and patients undergoing coronary revascularization (Table III). Peak wall stress and the time course of wall stress tended to be normalized postoperatively (Fig. 8), a fortuitous result of relative preservation of chamber radius/wall thickness (r/h) in our patients with eccentric hypertrophy. A tendency toward increased time to peak pressure and flow in chronic mitral regurgitation was not statistically significant. The rate of circumferential fiber shortening (Vcf) was significantly reduced at peak wall stress, as described previously by other investigators.[37] This reflects the fact that the relatively normal stroke volume in postoperative chronic mitral regurgitation is a small fraction of an enlarged end-diastolic volume (that is, ejection fraction is low). Additional differences in functional reserve might be defined by exploration of a wider range of filling pressures, but the large volume of data processing required precludes this at present. Because all patients in our study survived and only one required acute administration of inotropic agents, the mechanics observed may not be representative of the worst seen in patients with chronic mitral regurgitation.

The peak wall stress measurements reported here are low compared with the values of 265 to 560 g/cm^2 preoperatively and 280 g/cm^2 reported postoperatively by other investigators.[37,52,57,58] This is attributable to depressant effects of general anesthesia, the postischemic state immediately after cardiopulmonary bypass, and decreased left ventricular volume during surgery. The acute 39 percent increase in integrated left ventricular wall stress noted after elimination of mitral regurgitation (Table II) may be compared with an average 18 percent increase previously reported in dogs.[19]

The time course of wall stress postoperatively in both patients with chronic mitral regurgitation and

those with coronary disease was strikingly similar; it is strikingly dissimilar from the pattern of chronic mitral regurgitation preoperatively. The latter is thus identified as markedly anomalous in the spectrum of mechanics of human heart disease. This pattern of low impedence that artificially preserves ejection fraction, combined with increased left ventricular compliance that diminishes symptoms of pulmonary venous hypertension, apparently prolongs the time course of the illness to an extreme of left ventricular dysfunction.

Clinical Significance

Present criteria for determining the time of surgical intervention may be inadequate for optimal postoperative results in patients with chronic mitral regurgitation. Several attempts to define new criteria based on heart size or on velocity of circumferential shortening (Vcf) as measured in the catheterization laboratory have yet to be generally accepted. At present, a lower threshold of suspicion is needed to bring patients with chronic mitral regurgitation to earlier clinical attention. Further studies of left ventricular mechanics may help to define new standards for the timing of surgical intervention. Improvements in surgery, including better methods of myocardial preservation, improved valve prostheses and decreased overall morbidity and mortality would also strongly favor early valve replacement. Postoperative treatment of low output states in chronic mitral regurgitation should be directed at afterload reduction in addition to inotropic support, provided filling pressure is adequate. The use of vasopressor agents should generally be avoided.

The observed deterioration of left ventricular ejection fraction after correction of mitral regurgitation does not necessarily imply reduced cardiac output (forward output may actually increase) or clinical deterioration (most patients are symptomatically improved). However, results of surgery will be optimized if excessive unasked deterioration of left ventricular performance can be anticipated and avoided. The unusually high mortality and morbidity rates of surgery for mitral regurgitation suggest that general management of this condition can be improved. Although the depression of left ventricular function observed may reflect ischemia and other events at operation, these factors apply equally to the control patients examined. Furthermore, chronic depression of ejection fraction after correction of mitral regurgitation is well documented.[8,17,18]

Sources of Error

Intraoperative measurement of ventricular volume: The most difficult and important requirement for this study is accurate determination of ventricular volume intraoperatively. Measurement of instantaneous stroke volume is the least difficult, because flow velocity tracings are calibrated by simultaneous thermodilution stroke volume. The determination of end-diastolic volumes by nomogram must be considered less accurate, although the correlation coefficient (0.82) for the relation is satisfactory for our studies. Possible errors are further limited by calculating data for beats with left ventricular end-diastolic pressure close to the values obtained at angiography. However, it is important to point out that intraoperative measurements are obtained with the chest and pericardium open. Both of these changes may influence left ventricular compliance. Our experience suggests that these influences are small, but it is our custom to add 7 mm Hg to the left ventricular end-diastolic pressure observed at angiography to estimate the effects of negative intrapleural pressure and calculate true transmural filling pressure.

Measurement of regurgitant fraction: The greatest potential source of inaccuracy is in the quantitation and timing of that portion of left ventricular volume regurgitated into the left atrium. We have calculated this value from left ventricular end-systolic diameter and our nomogram relating diameter to volume. Calculations have been checked where possible with short axis cross-sectional area changes measured with two dimensional ultrasound and by correlation with regurgitant fraction and ejection fraction measured at preoperative angiography (Table I). The recognized lack of change in shape during systole in the relatively globular left ventricle of chronic mitral regurgitation suggests that the diameter-volume relation is less likely to change during systole with this condition. Whereas observations of decreased ejection fraction with M mode echocardiography alone could reflect paradoxical septal motion, confirmation of the observation with two dimensional echocardiography confirms the presence of global dysfunction of the left ventricle postoperatively.

Conclusions

Intraoperative studies of pressure, flow and echocardiographic dimensions in chronic mitral regurgitation indicate the following:

1. Left ventricular compliance may be increased in chronic mitral regurgitation, as suggested by a tendency toward rightward displacement of the end-diastolic pressure-diameter curve and increased value of the exponential constant.

2. Left ventricular ejection fraction is markedly decreased after mitral valve replacement when measured with either M mode or two dimensional echocardiography. This change is statistically significant when compared with findings in control groups consisting of patients with other common forms of surgical heart disease.

3. The decrease in left ventricular ejection fraction after valve replacement results from acutely increased afterload and elimination of a low impedance pathway to the left atrium.

4. Left ventricular systolic performance in patients with chronic mitral regurgitation is not lower postoperatively than that in patients after revascularization for coronary artery disease when indexes other than ejection fraction and velocity of circumferential shortening are analyzed.

5. Increased left ventricular mass and volume in chronic mitral regurgitation tend to normalize left ventricular wall stress during systole. Nevertheless,

ejection fraction is reduced after valve replacement. This indicates that factors other than peak force generation and pressure work cause decreased ejection fraction postoperatively. These factors may include chronic structural rearrangements in the left ventricular wall and other unrecognized variables.

6. These results emphasize the unreliability of preoperative ejection fraction as an index of cardiac reserve in chronic mitral regurgitation and suggest the need for improved methods of evaluating patients with this condition as candidates for surgery. Conventional analysis of ejection fraction preoperatively will lead to underestimation of the degree of left ventricular dysfunction.

Right Ventricular Performance in Mitral Stenosis

EDMUND WROBLEWSKI, MD
FRANK JAMES, MD
JAMES F. SPANN, MD, FACC
ALFRED A. BOVE, MD, PhD, FACC*

Philadelphia, Pennsylvania

Until recently, the dynamic geometry and pump function of the pressure-overloaded right ventricle in patients with mitral stenosis and pulmonary hypertension had not been well defined. With use of a recently developed method for calculating right ventricular volume in human beings, seven normal subjects and eight patients with mitral stenosis and pulmonary hypertension had right ventricular performance assessed from computer-analyzed biplane right ventriculograms. Patients with mitral stenosis had elevated values for systolic right ventricular pressure (mean ± standard error of the mean 25 ± 2 for normal subjects, 57 ± 6 mm Hg for patients with mitral stenosis), but normal values for right ventricular end-diastolic volume index (normal 95 ± 11, patients 81 ± 9 ml/m^2) and ejection fraction (normal 0.49 ± 0.02, patients 0.58 ± 0.04). Comparison of right ventricular function using group performance curves of stroke work versus end-diastolic volume revealed the slope of the mitral stenosis line to be significantly greater than the normal line. A plot of right ventricular stroke volume versus end-diastolic volume, which removes pressure from the performance index, revealed that the two groups have similar performance. Left ventricular function measured by ejection fraction was reduced in mitral stenosis. These data suggest that the right ventricle performs normally in patients with mitral stenosis with moderate pulmonary hypertension and maintains normal size and ejection fraction.

The clinical and hemodynamic effects of long-standing untreated mitral stenosis are well known.[1–4] It is also known that chronic pressure overload on the right ventricle because of mitral stenosis can result ultimately in right ventricular failure.[2–5] Although there has been extensive description of the clinical and hemodynamic status of the right ventricle subjected to chronic pressure overload, little is known about the contractile state of this chamber when the pressure overload is secondary to mitral stenosis.

Previous studies[6] evaluating the contractile state of the pressure overloaded right ventricle utilized pressure-dependent measurements to analyze right ventricular performance. However, such measurements may be misleading in the state of chronic pressure overload. Because the increased systolic load imposed on the right ventricle necessitates an augmented contractile response to maintain flow against higher resistance, the performance of the right ventricle, as assessed from pressure measurements, may appear normal or elevated.

In this study, we analyzed right ventricular performance in the state of chronic pressure overload using measurements of right ventricular volume as well as pressure. From this analysis, we have found that the contractile performance of the right ventricle in mitral stenosis remains normal with moderate pressure overload when there is no clinical evidence of right ventricular failure.

Methods

Study patients: The study is based on 14 patients who underwent diagnostic right and left heart catheterization including biplane right and left ventriculography. Seven patients had mitral stenosis as the only significant valve lesion. Patients with significant occlusive coronary artery disease were excluded. No

of the seven patients with mitral stenosis had clinical evidence of right ventricular failure (edema, hepatomegaly, ascites, right ventricular third sound). Two of the seven had minimal tricuspid regurgitation on right ventriculography. Three had atrial fibrillation, and four had normal sinus rhythm. The average heart rate was 91 ± 8.6 beats/min (the range was 60 to 120). Seven patients with normal right and left heart pressures and normal findings on right and left ventriculography and coronary arteriography served as control subjects.

Catheterization procedure: All patients underwent diagnostic cardiac catheterization using the right brachial technique.[7] Left heart catheterization was performed with a 7F National Institutes of Health catheter. Biplane 60 frame/s left ventriculography was performed using Renografin® -76 injected at 12 to 16 cc/s for 3 seconds, with the patient in the 60° left anterior oblique and 30° right anterior oblique positions. After coronary arteriography and repair of the brachial arteriotomy, right ventriculograms were exposed at 60 frames/s with the patient in the 60° left and 30° right anterior oblique positions using Renografin-76 injected at 12 to 16 cc/s for 3 seconds. Pressure measurements in both ventricles were obtained with Statham p23dB fluid-filled transducers connected to the ventricular catheters. Right ventricular pressure measurements were made with a 7F fluid-filled pigtail catheter connected to Statham p23dB pressure transducers with a zero reference at the level of the mid chest.

Right ventricular volume analysis: One and one-half cardiac cycles beginning at the peak of the electrocardiographic R wave were analyzed. Ventriculographic outlines from each frame of the biplane films were digitized with a digital plotting table connected to a computer.[8] The two ventricular outlines were traced with a magnetic cursor and the geometric data were stored on digital tape. Volume analysis for the right ventricle is based on an area-length method that we[9] previously described. To calculate stroke work, a right ventricular pressure wave form was digitized and superimposed on the already stored ventriculographic image data. Calculation of stroke work was done using the formula: $SW = \Sigma\, p\,dv$, where p is instantaneous pressure in a given 1/60 second interval and dv is the change in volume over the same interval. The value for dv is calculated by determining the first derivative of a second order curve drawn through the volume curve in the region of analysis. Further details of this calculation are given in a previous study.[8] The integral of the work versus time curve from end-diastole to end-systole provides the stroke work. End-diastole and end-systole were determined from the volume versus time curve. End-diastolic, end-systolic and stroke volumes were also obtained from the curve of right ventricular volume versus time constructed from the frame by frame analysis.

Left ventricular ejection fraction was calculated from the end-diastolic and end-systolic frames in the left and right anterior oblique views. The left ventricular volumes were determined using the formula of Dodge et al.[10]

Statistical analysis: For comparisons between normal subjects and patients with mitral stenosis, nonpaired *t* tests were used. Linear regression was used to derive the slopes of the ventricular function curves. Data are expressed as mean values ± standard error of the mean.

Results

Left heart pressures and volumes (Table I): There was no significant difference between the left ventricular end-diastolic volume index of the patients with mitral stenosis and the control group, whereas the left ventricular end-systolic volume index was slightly higher in the patient group. There was no significant difference between the left ventricular stroke volume index of the patients and control subjects. The left ventricular ejection fraction was lower in the patients than in the control subjects ($p < 0.05$). There was no significant difference between the peak systolic pressure or end-diastolic pressure of the left ventricles of the two groups.

Right heart pressures and volumes (Table II): The mean pulmonary arterial wedge pressure for the patients with mitral stenosis was 23.3 ± 2.3 mm Hg and the mean mitral valve gradient at rest averaged 11.9 ± 1.6 mm Hg. The average mitral valve area calculated from the Gorlin formula[11] was 1.0 ± 0.17 cm^2. Right ventricular ejection fraction in the patients was somewhat higher than that in the control subjects ($p < 0.10$), but there was no difference between the right ventricular end-diastolic volume index and right ventricular stroke volume index of the two groups. The end-systolic volume index was somewhat lower in the patients than for the control group, but this difference was not significant. Average right ventricular systolic pressure was

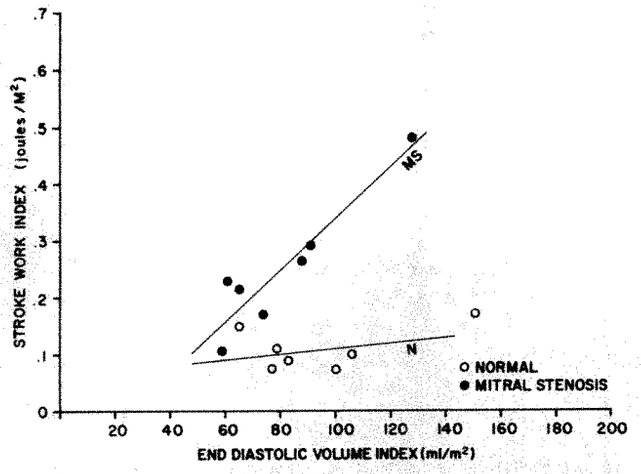

FIGURE 1. Comparison of right ventricular function in seven normal subjects (N) and seven patients with mitral stenosis using group performance curves of stroke work versus end-diastolic volume. The slope of the mitral stenosis (MS) line is significantly greater than the normal (N) slope.

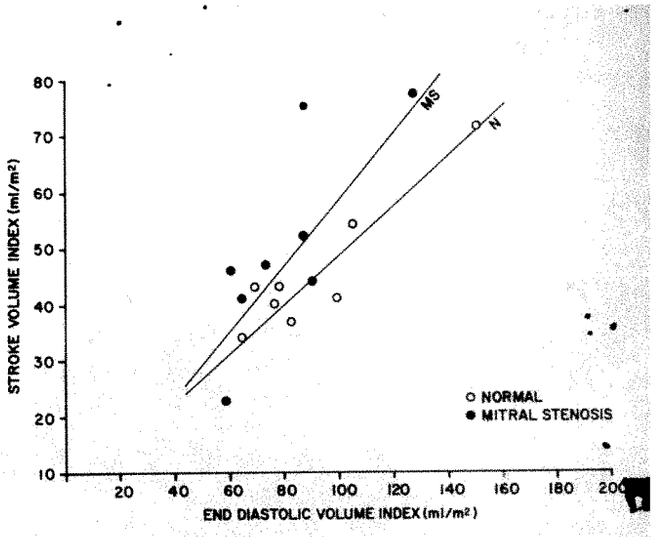

FIGURE 2. Comparison of right ventricular function in normal subjects (N) and patients with mitral stenosis (MS) using group performance curves of stroke volume versus end-diastolic volume. When pressure is removed from the performance measurement, the two groups have similar contractile performance.

significantly higher in the patients. The mean right ventricular end-diastolic pressure in the patients was slightly higher than that in the control group, although this value remained within the normal range and the difference was not significantly different.

Right and left ventricular performance: *Right ventricle:* A plot of stroke work index versus end-diastolic volume index for patients with mitral stenosis and for the normal control subjects (Fig. 1) revealed a significantly higher slope in the patients (normal = 5.54 ± 5.13, patients = 45.15 ± 8.00; $p < 0.005$). The slope of stroke volume index versus end-diastolic volume index for the patients and control subjects (Fig. 2) showed no significant difference between groups (normal = 0.430 ± 0.63, patients = 0.586 ± 0.143). Right ventricular peak rate of pressure development (dP/dt) was increased (Table II) in the patients.

Left ventricle: A plot of left ventricular stroke volume index versus end-diastolic volume index in the patients with mitral stenosis and the control subjects (Fig. 3) revealed a slightly lower slope in the patient group; however, the difference was not significant (normal = 0.675 ± 0.124, patients = 0.527 ± 0.176).

Discussion

Right ventricular volume and pump performance in chronic pressure overload: Our observations demonstrate that the right ventricle maintains normal volume and contractile performance in the presence of moderate pressure overload induced by mitral stenosis. Although it is known that a prolonged severe systolic overload can result in right ventricular failure with edema, ascites, hepatic congestion and venous distension, our study did not include patients with fulminant right ventricular failure. Whereas right ventricular performance studies are rare, studies of left ventricular contractile function in chronic pressure overload have demonstrated that left ventricular contractile performance remains normal until overt clinical failure occurs.[12,13] Data from our laboratory[13] also indicate that left ventricular volume remains normal despite chronic pressure overload to the left ventricle unless overt failure is present. Thus, the ventricles appear to respond similarly when subjected to chronic pressure overload. The data of Sasayama et al.[14] in dogs indicated that the right ventricle functions normally in states of m pressure overload and, in cats, Williams and Potter found normal right ventricular function after 24 wee of moderate pressure overload even though function w initially depressed. Our data in the present stu

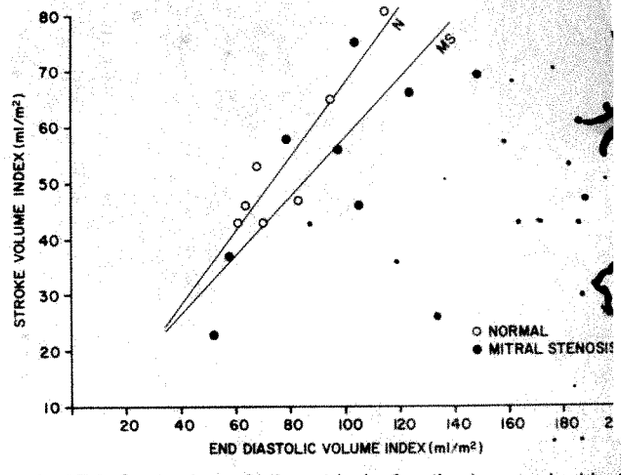

FIGURE 3. Comparison of left ventricular function in normal subjects (N) and patients with mitral stenosis (MS) using group performance curves of stroke volume versus end-diastolic volume. Although the slope of the mitral stenosis line is lower than the normal slope, the difference did not reach statistical significance.

demonstrate that right ventricular volume and right ventricular pump performance are normal with moderate pressure overload and in the absence of overt clinical right ventricular failure. Normal right ventricular pump function with moderate systolic pressure elevation may progress to decreased function when the pressure load becomes severe. Other clinical[12,13] and animal[16,17] studies of chronic pressure overload have shown that ventricular performance is a function of the severity of the overload.

Assessment of right ventricular performance: The assessment of intact right ventricular performance in the presence of chronic pressure overload is difficult. Pressure-related indexes such as peak right ventricular pressure, dP/dt, stroke work and stroke power will always suggest augmented performance because of the elevated systolic pressure. The right ventricle must generate excess pressure to maintain forward blood flow. This increased pressure generation is usually made possible by increased myocardial mass (hypertrophy), and measurement of pressure does not allow assessment of the contribution of increased muscle mass to performance.

A recent study by Stein et al.[6] using pressure-based performance characteristics demonstrated normal contractile function of the right ventricle in patients with pulmonary hypertension including nine with clinical right ventricular failure. They used plots of right ventricular dP/dt versus end-diastolic pressure to determine ventricular performance. Nine of their patients had overt clinical failure but showed normal function on the basis of pressure measurements.

We[18] have previously used plots of stroke volume versus end-diastolic volume to assess intact left ventricular performance in animal studies where systolic pressure was elevated. These volume curves applied to the present right ventricular data (Fig. 2) show that right ventricular function is normal in mitral stenosis without overt right ventricular failure.

Although normal right ventricular pump performance was demonstrated in our patients, we cannot state with certainty that muscle performance of the right ventricle is normal. A disparity between pump and muscle performance may occur, for example, when normal pump performance is maintained by hypertrophy of poorly performing muscle units. It was impossible in the present study to assess the degree of right ventricular hypertrophy.

Left ventricular performance in mitral stenosis: Although this study was primarily concerned with right ventricular performance, we noted (Table I) that the left ventricular ejection fraction of the patients with mitral stenosis was lower than that of normal subjects. Abnormal left ventricular function in patients with mitral stenosis[19–21] has previously been reported, but its cause is not clear. It is possible that a pressure overload to the right ventricle in some way affects the left ventricle through changes in right ventricular shape that may be reflected into the left ventricle through the shared interventricular septum.[22] The left ventricle of these patients may also have been affected by inflammatory changes at the time of active rheumatic disease[23,24] or by fibrosis of the chordae tendineae and papillary muscles.[25] Finally, it is possible that the pump function of the left ventricle may be affected by a decrease in inflow to the left ventricle because of valve obstruction.[26]

In summary, we have demonstrated that the right ventricle functions normally when subjected to chronic pressure overload due to mitral stenosis. This normal function is probably maintained by hypertrophy when the pressure overload is not extreme. In addition, left ventricular performance appears to be diminished in mitral stenosis, and the cause of this reduced left ventricular function is not clear.

Right Ventricular Function in Adult Atrial Septal Defect

Preoperative and Postoperative Assessment and Clinical Implications

Right ventricular function was assessed with gated cardiac blood pool scanning in 20 adult patients with an atrial septal defect. All patients had scans both before and 6 or more months after surgical repair of the defect. Clinical findings, pre- and postoperative course and cardiac catheterization data were correlated with scan findings. In all 20 patients, the right ventricle was dilated preoperatively. In nine patients (aged 18 to 42 years, mean 25), right ventricular wall motion was normal preoperatively. All nine were asymptomatic and had normal sinus rhythm. Their pulmonary to systemic flow ratio ranged between 2:1 and 5:1, pulmonary arterial systolic pressure between 18 and 30 mm Hg and right ventricular end-diastolic pressure between 0 and 8 mm Hg. After repair of the atrial septal defect, all nine remained asymptomatic, right ventricular size decreased dramatically and wall motion was normal.

In the remaining 11 patients (aged 36 to 63 years, mean 52), there was moderate to severe preoperative right ventricular hypokinesia. All had preoperative symptoms (functional class II and III, New York Heart Association); six had atrial fibrillation and five had normal sinus rhythm; seven had clinical heart failure. Pulmonary to systemic flow ratio ranged between 1.7:1 and 5.0:1, pulmonary arterial pressure between 26 and 70 mm Hg and right ventricular end-diastolic pressure between 4 and 16 mm Hg. Symptoms were lessened and right ventricular size and function improved postoperatively in these 11 patients. Unlike those with normal preoperative right ventricular wall motion, however, only 1 of the 11 had normal postoperative right ventricular function and became asymptomatic.

Most patients with isolated atrial septal defect undergo elective surgical repair during childhood or early adult life before either symptoms or complications develop. In such patients postoperative complications are uncommon.[1–3] In contrast, older adults with an uncorrected atrial septal defect frequently have symptoms and pre- and postoperative complications, particularly atrial arrhythmias and right heart failure.[4–9] Although these symptoms and complications are generally attributed to chronic right heart volume overload, to our knowledge right ventricular systolic function has not previously been systematically studied in these patients.

Gated cardiac blood pool imaging has been extensively used to assess right ventricular function in a wide range of cardiac lesions,[10–14] and is well suited to the noninvasive assessment of right ventricular size and function in patients with atrial septal defect. In this study, we assessed right ventricular function using gated cardiac blood pool imaging in 20 patients before and after repair of an atrial septal defect, and correlated these findings with clinical and catheterization data and with the postoperative course.

Methods

Study patients: Twenty patients (aged 18 to 63 years) with isolated secundum atrial septal defect documented by cardiac catheterization or surgery, or both,

were studied. A preoperative gated cardiac blood pool scan was performed at the time of cardiac catheterization in all patients, and a postoperative follow-up scan was performed 6 months after surgical correction. Pre- and postoperative clinical course, cardiac medications, physical examination, cardiac rhythm and cardiac catheterization findings were reviewed and correlated with data obtained from the gated cardiac scan. Symptoms and functional class were categorized according to standard New York Heart Association criteria.[15] Right heart failure was defined by abnormal elevation of jugular venous pressures, hepatomegaly, ascites and edema.

Imaging techniques: Radionuclide scanning was performed after intravenous administration of 20 millicuries of either technetium-99m labeled human serum albumin or in vivo labeled red blood cells.[16] Gated scans were recorded at only end-systole and end-diastole in the initial 13 patients; the last 7 patients had multigated scans. Studies were recorded with an all purpose collimator using a 20 percent window centered at the 140 KeV photopeak of technetium-99m. The data were recorded using a dedicated nuclear medicine computer PDP-9 system for the initial 12 patients, and an Ohio Nuclear VIP-450 in the last 8. In the latter eight patients, the initial passage of tracer through the right side of the heart was recorded in the right anterior oblique projection in a multiple gated acquisition sequence during the first 5 to 10 beats after the tracer injection.

Assessment of right ventricular function: Although there have been some published reports proposing criteria for assessing right ventricular size and contraction by gated cardiac scan,[12,17] quantitative criteria have not been universally agreed on. Thus, in this study, we relied primarily on the subjective assessment of the experienced nuclear medicine physician. Scans were interpreted independently by us on three separate occasions without knowledge of the patients' clinical or catheterization findings. There was no significant interobserver variability in interpretation. There were no discernible differences in our results using either method of cardiac imaging, that is, end-systolic and end-diastolic differences in the initial 13 patients versus estimation of these points from the multigated scans performed in the last 7 patients.

Right ventricular size was subjectively graded as normal (Fig. 1B) or dilated (Fig. 1A, 3A, 3B). In addition, subjective observations were supplemented by more quantitative evaluation by comparing the right ventricular and left ventricular areas determined with planimetry at end-diastole in the left anterior oblique projection. Previous work[12] indicates that the normal right ventricular size only slightly exceeds left ventricular size, with the ratio of normal right ventricular to left ventricular size being 1.11 ± 0.06 (mean ± 1 standard deviation). In patients with an isolated atrial septal defect, left ventricular size is typically normal; therefore this ratio was used as a measure of right ventricular size.

Right ventricular contraction was assessed subjectively and graded as normal (Fig. 1 and 2) or hypocontractile (Fig. 3 and 4). A more quantitative assessment of right ventricular contraction was also made by calculating the right ventricular ejection fraction in eight patients who had gated first pass

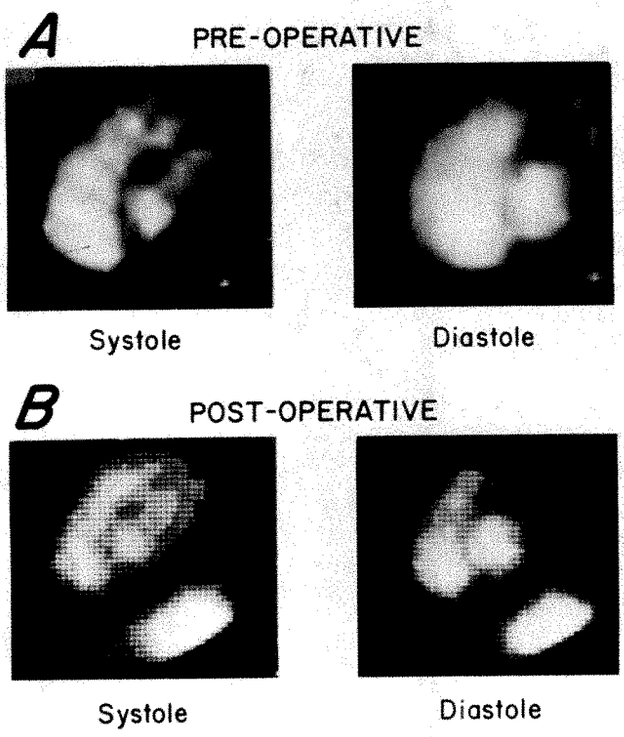

FIGURE 1. Pre- (**A**) and postoperative (**B**) equilibrium gated cardiac blood pool scan in the left anterior oblique projection in a 25 year old woman with an atrial septal defect. Preoperatively, the right ventricle is dilated (right ventricle/left ventricle ratio = 2.15/1) but has normal wall motion (ejection fraction = 64 percent). The postoperative scan performed 6 months after surgical repair reveals decreased right ventricle size (right ventricle/left ventricle ratio = 1.36/1), and normal right ventricular contraction (ejection fraction = 65 percent).

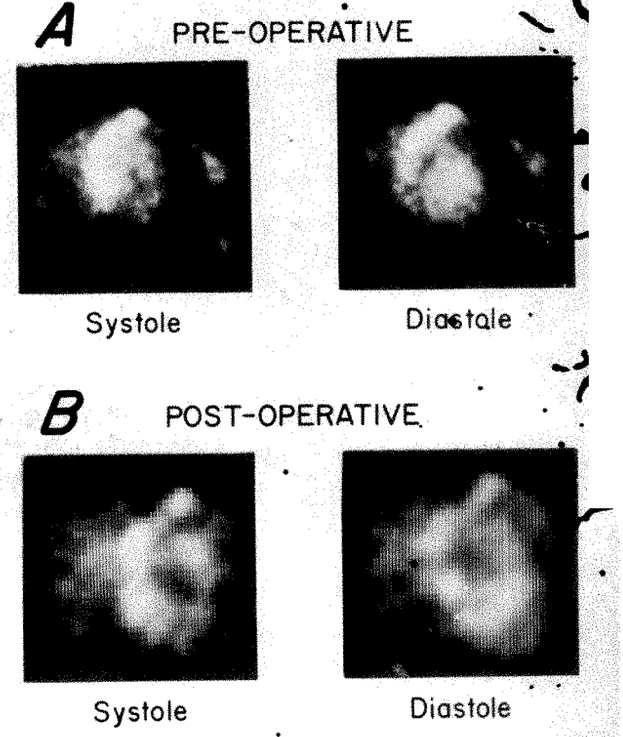

FIGURE 2. Pre- (**A**) and postoperative (**B**) gated first pass flow scans in the right anterior oblique projection in a 36 year old woman with an atrial septal defect, illustrating normal pre- and postoperative right ventricular contraction with an ejection fraction of 58 and 64 percent, respectively.

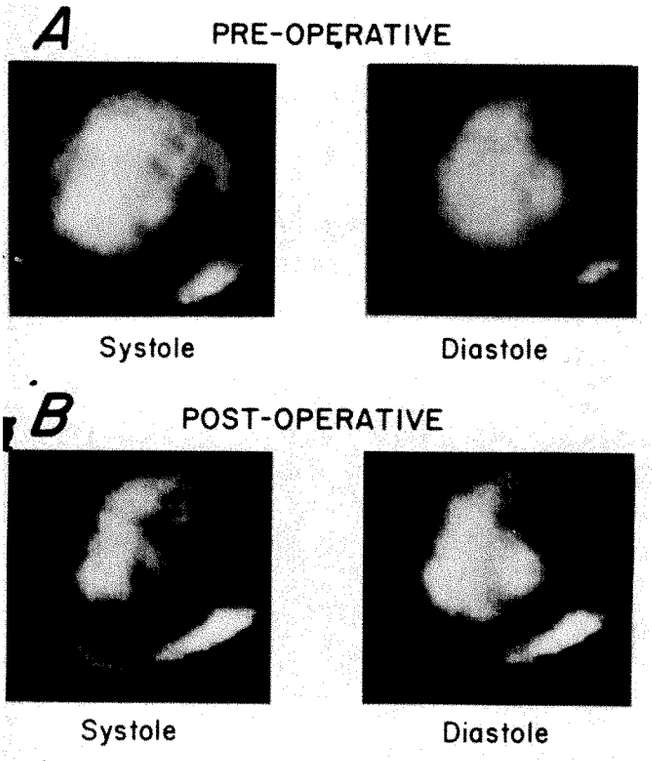

FIGURE 3. Pre- (**A**) and postoperative (**B**) gated cardiac blood pool scans in the left anterior oblique projection in a 58 year old woman with an atrial septal defect, moderate pulmonary hypertension and heart failure. Preoperatively, the right ventricle is markedly dilated (right ventricle/left ventricle = 3.5:1) and severely hypokinetic (ejection fraction = 36 percent). Postoperatively (after 6 months), there is a decrease in right ventricular size (right ventricle/left ventricle ratio = 3.0:1) but persisting right ventricular hypokinesia (ejection fraction = 50 percent).

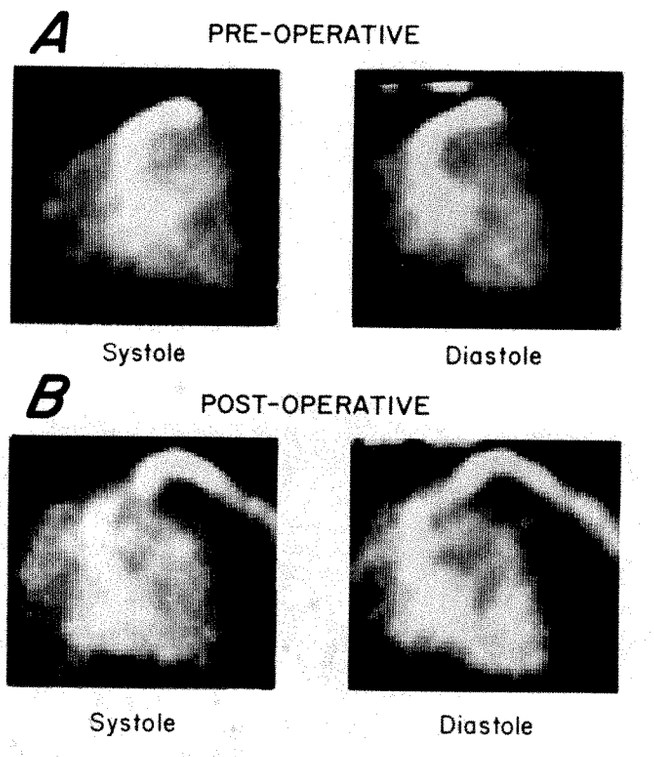

FIGURE 4. Pre- (**A**) and postoperative (**B**) gated first pass flow scans in the right anterior oblique projection in a 52 year old woman with an atrial septal defect illustrating decreased pre- and postoperative right ventricular contraction with an ejection fraction of of 46 and 45 percent, respectively.

ans. In these patients, right ventricular ejection fraction was calculated using a previously reported method[17] in which ejection fraction was determined as the difference between end-systolic and end-diastolic counts in the right ventricular region in the right anterior oblique first pass study. With this technique, normal right ventricular ejection fraction in our laboratory is 60 ± 7.0. In addition, right ventricular ejection fraction was determined by the difference between end-systolic and end-diastolic area determined by planimetry in the left anterior oblique projection. This value did not differ significantly from the ejection fraction determined using the counts method.

Results

Subjective preoperative right ventricular dilation of varying magnitude was present in all patients (Fig. 1A and 3A). The ratio of planimetered right ventricular to left ventricular area in these patients ranged between 1.89 and 3.50:1. Assessment of preoperative right ventricular wall motion separated patients into two clinically and hemodynamically distinct subgroups.

Patients with normal right ventricular wall motion: Nine patients (aged 18 to 42 years, mean 25) had normal right ventricular wall motion, inspite of varying degrees of dilation (Fig. 1A and 2A). The ratio of planimetered preoperative right ventricular to left ventricular areas ranged between 1.84 and 2.15:1 (mean 2.0:1) and the calculated preoperative ejection fraction ranged between 58 and 70 percent (mean 64). All patients were asymptomatic and none had heart failure or arrhythmias. Nine required cardiac medication. Pulmonary-to-systemic flow ratio ranged between 2 and 5:1, pulmonary artery systolic pressure between 18 and 30 mm Hg, (mean 23 mm Hg), pulmonary artery resistance was less than 2 units · m^2 in all patients, and right ventricular end-diastolic pressure was between 0 and 8 mm Hg (mean 3). All patients had uncomplicated repair of the atrial septal defect, none had postoperative symptoms or complications, and the postoperative scans revealed marked decrease in right ventricular size (Fig. 1B) and normal right ventricular wall motion (Fig. 1B, 2B). The ratio of planimetered postoperative right ventricular to left ventricular areas was between 1.36 and 1.43:1 (mean 1.40) and postoperative right ventricular ejection fraction was between 64 and 66 percent, (mean 65).

Patients with right ventricular hypokinesia: Eleven patients (aged 36 to 63, mean 52) had diffuse preoperative right ventricular hypokinesia (Fig. 3A, 4A). Planimetered preoperative right ventricular to left

ventricular area ratio in these patients was between 2.81 and 3.50:1 (mean 3.10:1). Preoperative ejection fraction was between 31 and 47 percent (mean 34 percent). All of these patients had preoperative exertional fatigue and dyspnea (functional class II or III); five were in atrial fibrillation and six in normal sinus rhythm. Seven patients had clinical findings of heart failure consisting of elevated jugular venous pulse and hepatomegaly, and two patients had ascites, edema, and tricuspid incompetence. Nine patients required digitalis preparations and five also required diuretics. Pulmonary to systemic flow ratio ranged between 1.7 and 5.0:1; pulmonary artery systolic pressures between 26 and 70 mm Hg (mean 43); pulmonary artery resistance between 2 and 5.5 units · m^2 (mean 3.8); and right ventricular end-diastolic pressure between 4 and 16 mg Hg (mean 11).

Symptoms improved in all patients after surgical repair and they were either in functional class I or II but only one patient (age 36 years) became asymptomatic. Atrial fibrillation persisted postoperatively in the five patients who had preoperative atrial fibrillation and the remaining patients remained in normal sinus rhythm. Digitalis preparations were continued in nine patients and diuretics in three. The postoperative scan showed subjective decrease in right ventricular size in all patients but still significant dilation, and all had persistent right ventricular hypokinesis (Fig. 3B, 4B). The ratio of postoperative right ventricular to left ventricular planimetered area was between 1.5 and 3.0:1 (mean 2.20:1). Postoperative right ventricular ejection fraction was between 44 and 51 percent (mean 47), which was a significant increase compared to preoperative right ventricular ejection fraction ($p < 0.05$).

Discussion

Right ventricular function following repair of atrial septal defect: Although it is presumed that chronic right ventricular volume overload causes impairment of right ventricular ejection in the adult with atrial septal defect, and that this explains their symptoms and complications, there have been few systematic studies of right ventricular function in these patients. Preoperative right ventricular wall motion in our patients varied from normal to reduced. Preoperative right ventricular wall motion divided patients into two groups in terms of pre- and postoperative symptoms and complications, and normal versus abnormal postoperative right ventricular function. Right ventricular wall motion was normal in the asymptomatic younger patients even though the right ventricle was enlarged. These patients remained asymptomatic after surgery, right ventricular size decreased dramatically, and right ventricular wall motion remained normal. In contrast, patients with decreased preoperative right ventricular wall motion were older and had pre- and postoperative symptoms or complications, or both. In these patients, postoperatively right ventricular dilation also decreased and right ventricular wall motion and symptoms improved; however, right ventricular function did not become normal. Although symptoms improved postoperatively, these patients did not become asymptomatic.

Prior studies have evaluated postoperative right ventricular size using M mode echocardiography,[18] and findings in both the young[19] and older[20] patient with atrial septal defect closely mirror our findings using gated cardiac imaging. However, as demonstrated in the present study, right ventricular function appears to be an important predictor of pre- and postoperative clinical status in these patients and this has not previously been systematically assessed using a noninvasive radionuclide approach. Selective right ventricular angiography is suitable for evaluating right ventricular contraction, but in the older patient with heart failure and elevated pulmonary artery pressure it is not without risk.[21] Two dimensional echocardiography may also be helpful in assessing right ventricular size and wall motion[22]; however, to our knowledge it has not yet been systematically applied to these patients.

Clinical implications: Our observations strongly support the present widespread clinical practice of early prophylactic closure of atrial septal defect. Furthermore, in spite of only partial postoperative improvement in symptoms and right ventricular size and function in patients with abnormal preoperative right ventricular wall motion, our findings also argue strongly for surgical repair in these patients.

The correlation between right ventricular wall motion and postoperative improvement in right ventricular size and function in patients with atrial septal defect observed in our study is analogous to the correlation between preoperative left ventricular wall motion and postoperative improvement of left ventricular size and function in patients with aortic insufficiency.[23,24] In the latter, decreased preoperative left ventricular wall motion also indicates that postoperative left ventricular function may not normalize.

Of note was the presence of right ventricular hypokinesis in four patients who had clinical right ventricular failure with elevated right ventricular end-diastolic pressure, but who had normal pulmonary artery pressure (less than 30 mm Hg), pulmonary arteriolar resistance between 2 and 4 units · m^2, and normal coronary arteries. These patients illustrate the not widely appreciated fact that severe pulmonary hypertension is not the only cause of right ventricular failure in atrial septal defect.[1,8,25]

In summary, this study illustrates the close correlation between right ventricular function and clinical course in both pre- and postoperative patients with atrial septal defect. Nuclear imaging is helpful in assessing the older symptomatic adult. In these patients, the demonstration of severe preoperative right ventricular hypocontractility indicates that, although postoperative right ventricular size and function improve, neither becomes normal.

Acknowledgment

We thank Bill Shea for his technical assistance and Shannon L. Riley for her assistance in the preparation of this manuscript.

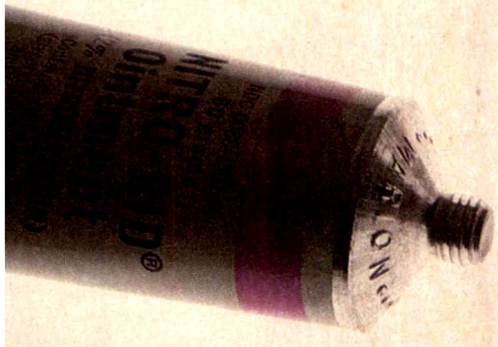
In angina pectoris...

NITRO-BID®
(2% nitroglycerin)
Transdermal Ointment

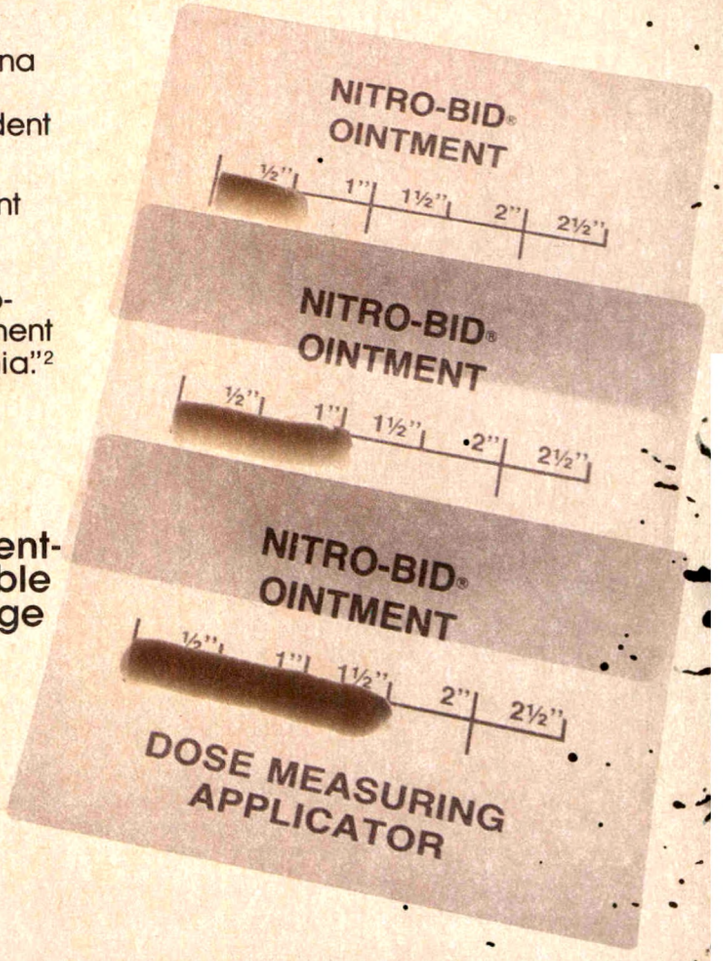
For prolonged prophylactic action

"Cutaneous administration of Nitroglycerin ointment (NITRO-BID®) in patients with angina pectoris exhibits prolonged action with evidence of pharmacological activity evident up to eight hours after application."[1]

"...data indicate that nitroglycerin ointment (NITRO-BID®) exerts profound reduction of peripheral arteriolar and venous tone with resultant alterations in left ventricular hemodynamic variables which afford enhancement of exercise tolerance and reduced ischemia."[2]



Patient-titratable dosage



Brief Summary:

Description: Nitroglycerin 2% (glyceryl trinitrate) and lactose in a special absorptive lanolin and white petrolatum base.

Action: Nitroglycerin is continuously absorbed through the skin into the circulation, thus exerting prolonged vasodilator effects.

Indications: For the prevention and treatment of angina pectoris due to coronary artery disease.

Contraindications: In patients known to be intolerant of the organic nitrate drugs.

Warnings: In acute myocardial infarction or congestive heart failure, nitroglycerin ointment should be used under careful clinical and/or hemodynamic monitoring.

Precautions: Symptoms of hypotension, particularly when suddenly arising from the recumbent position, are signs of overdosage. When they occur, the dosage should be reduced.

Adverse Reactions: Transient headaches are the most common side effect, especially at higher dosages. Headaches should be treated with mild analgesics, and nitroglycerin ointment continued. Only with untreatable headaches should the dosage be reduced. Although uncommon, hypotension, an increase in heart rate, faintness, flushing, dizziness, and nausea may occur. These all are attributable to the pharmacologic effects of nitroglycerin on the cardiovascular system, but are symptoms of overdosage. When they occur and persist, the dosage should be reduced.

Dosage: Usual dose is 2 inches (50mm), as squeezed from the tube, every eight hours. Some patients may need 4 to 5 inches (100 to 125 mm) and/or application every four hours. Optimal dosage should be based upon clinical response, side effects, and effects of therapy upon blood pressure. Consult full product disclosure before prescribing.

around a Star

r™ system, developed by General Electric, ets the data processing needs of today's nuclear artment. It interfaces with the GE line of ieras to greatly advance diagnostic capability.

n Star at the center of your department you have essential tool for studies requiring quantitative out like renal analysis and for complex cedures like multigated cardiac studies.

r's advanced clinical protocols dramatically ease diagnostic information and accuracy le saving you precious time.

G.E. (Program for Automatic Gated Evaluation) completely automatic cardiac acquisition and lysis program.

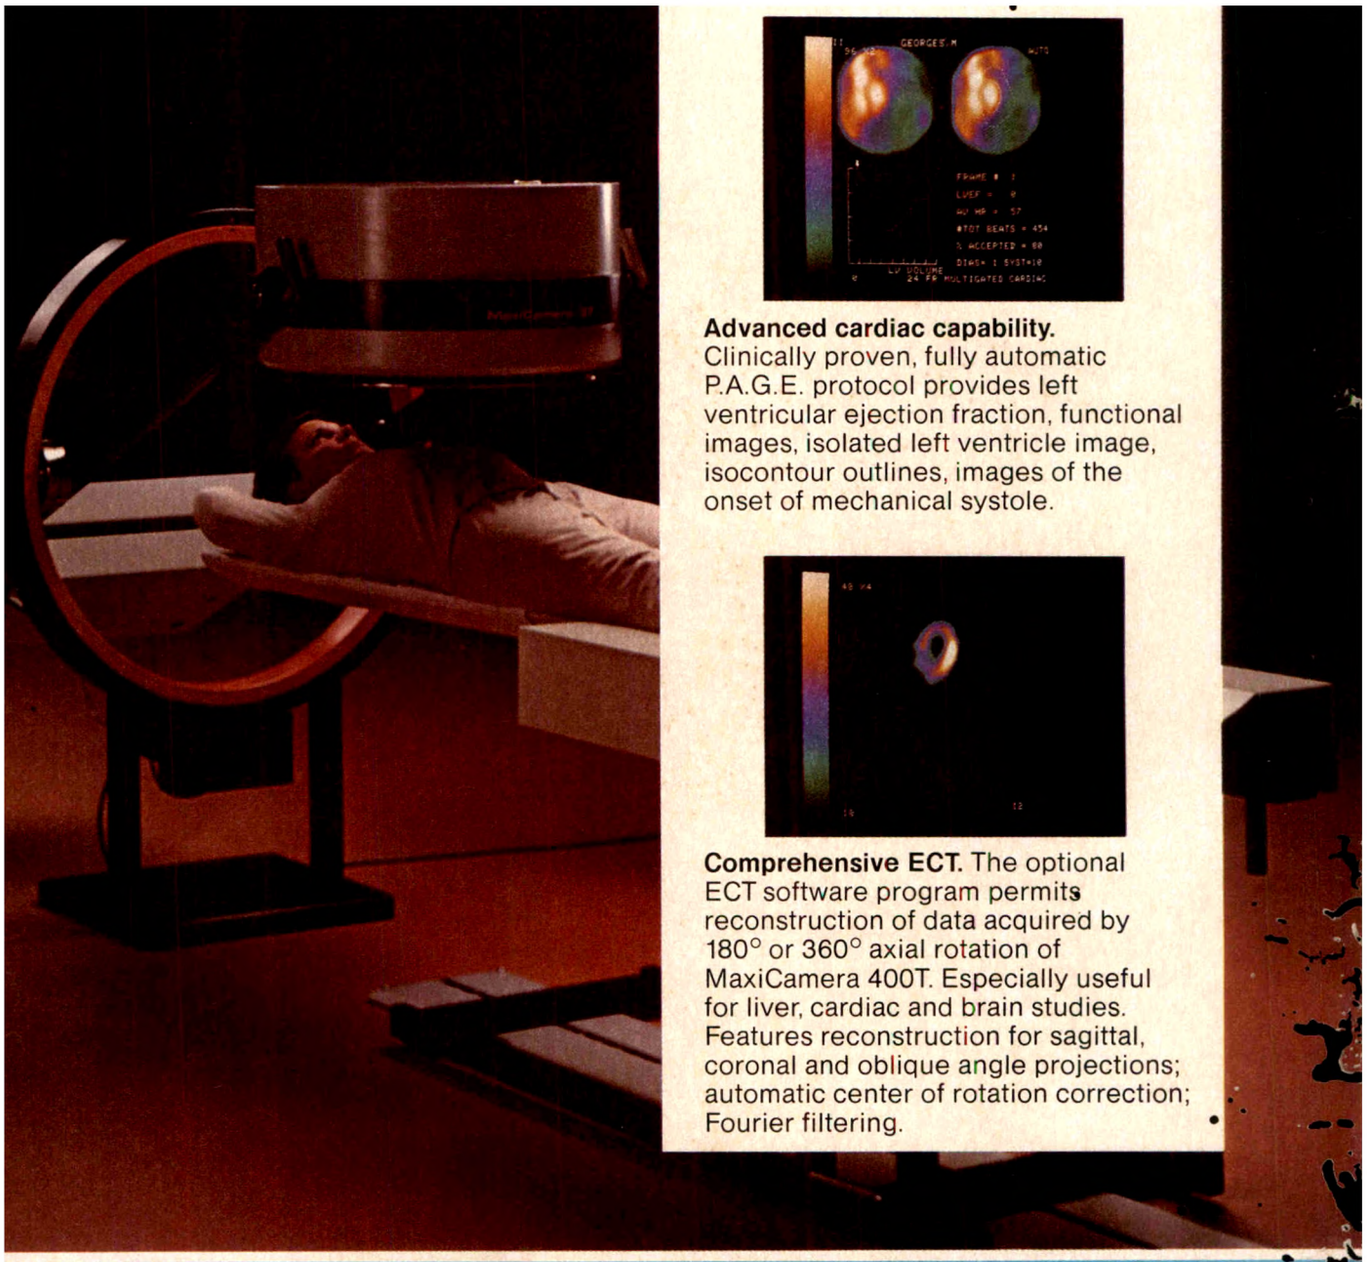
First pass cardiac simplifies data processing for rapid assessment of this cardiac procedure.

Ventilation/perfusion automatically calculates and displays ventilation regions, curves, parameters and ventilation/perfusion subtraction.

Renal function has been clinically validated for accuracy in effective renal plasma flow, bladder analysis, glomerular filtration rate and filtration fraction.

Emission computed tomography (ECT) is an optional program for reconstruction of data acquired with the MaxiCamera™ 400T.

Besides outstanding software, you get outstanding image quality from the full array



Advanced cardiac capability. Clinically proven, fully automatic P.A.G.E. protocol provides left ventricular ejection fraction, functional images, isolated left ventricle image, isocontour outlines, images of the onset of mechanical systole.

Comprehensive ECT. The optional ECT software program permits reconstruction of data acquired by 180° or 360° axial rotation of MaxiCamera 400T. Especially useful for liver, cardiac and brain studies. Features reconstruction for sagittal, coronal and oblique angle projections; automatic center of rotation correction; Fourier filtering.

of image enhancement features including: selectable hardware interpolation; image window/leveling; user-definable filters and display maps.

Star also lets you predefine commands so you can perform routine departmental procedures with a touch of a key. And, Star system speaks your language. You "talk" to the computer with function keys and it guides you through operations in English, step by step. No computer language or codes. Simple. Accurate.

Ask your GE representative to show you how to build your department around the Star.

Be sure to attend a Star performance at the ACC meeting, San Francisco, March 16-19, 1981.

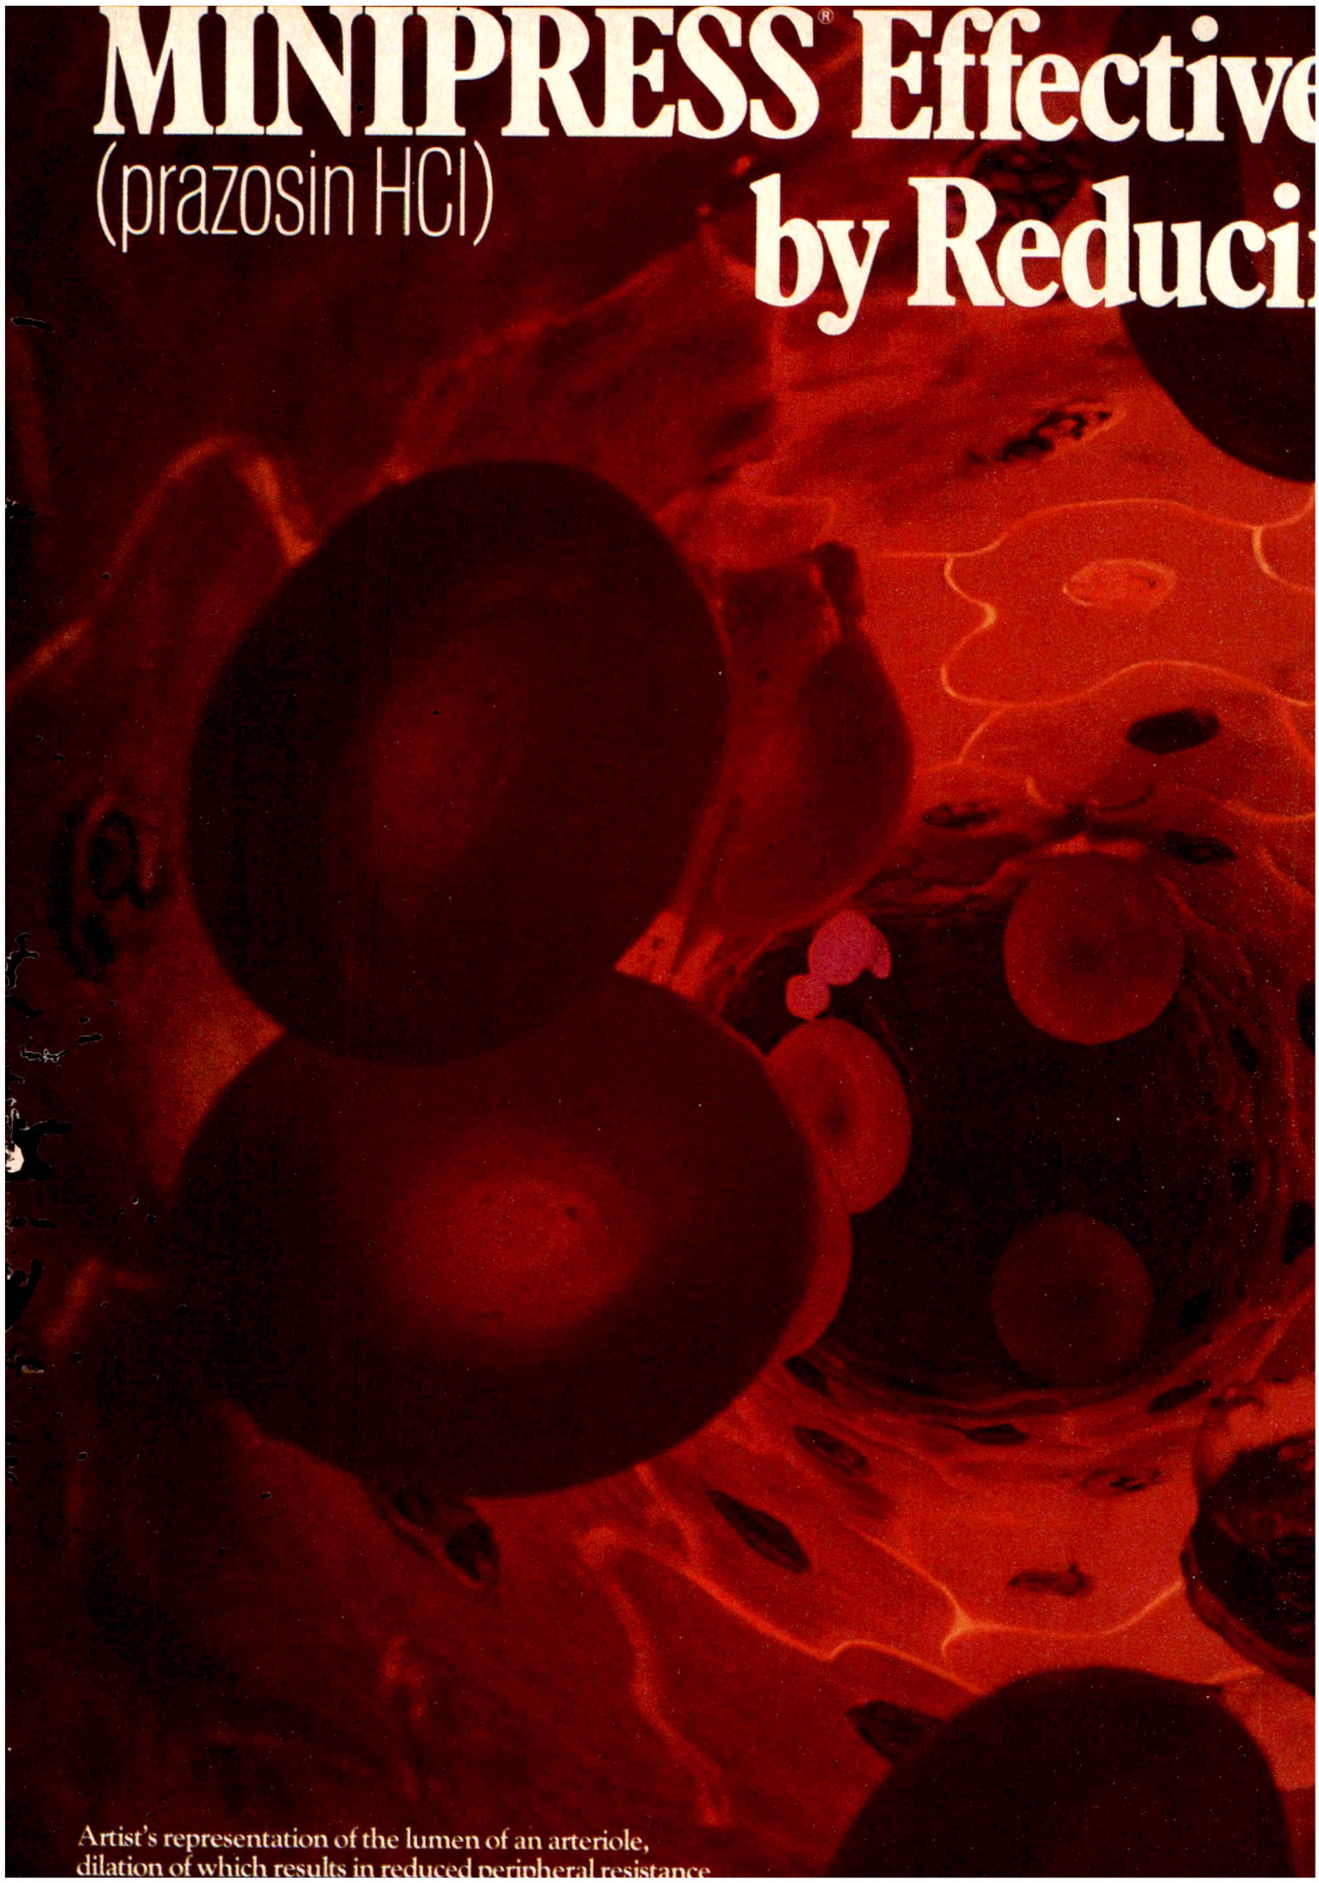
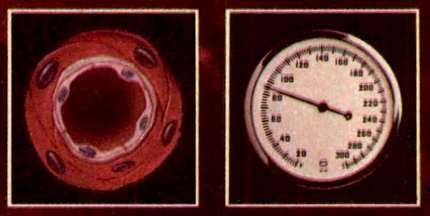
MINIPRESS® Effective
(prazosin HCl)
by Reduci



Artist's representation of the lumen of an arteriole, dilation of which results in reduced peripheral resistance

Controls Hypertension Peripheral Resistance



- MINIPRESS Reduces Mean Arterial Pressure
- MINIPRESS Reduces Total Peripheral Resistance
- MINIPRESS Does Not Reduce Cardiac Index

...and Maintains These Effects Over the Long Term

Relative hemodynamic changes at rest and during exercise after one year of prazosin therapy in 10 hypertensive patients. Adapted from Lund-Johansen[1]

Rest Exercise

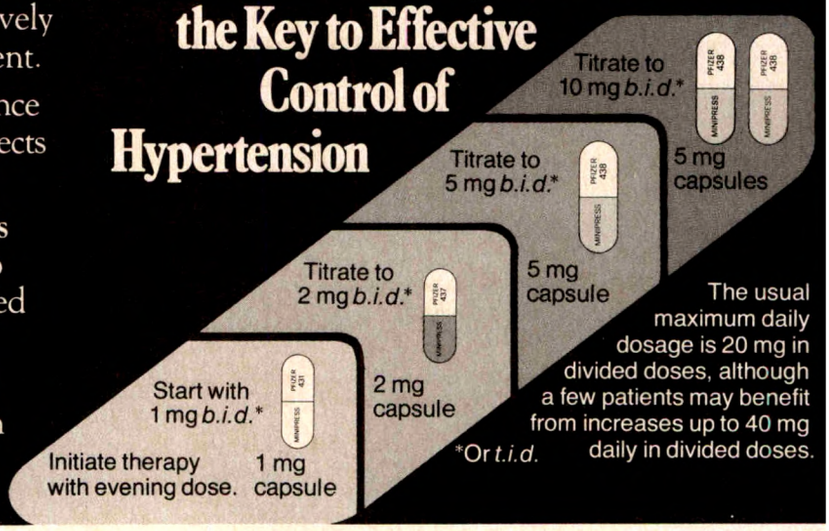
MINIPRESS®

(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

MINIPRESS
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

- **Effectively lowers elevated blood pressure by reducing peripheral resistance.**
- **Maintains cardiac output** which allows patients to maintain an active life style.
- **Maintains renal blood flow and glomerular filtration rate** so it can be used effectively even in patients with renal impairment.
- **Not a CNS agent** so patients experience few of the troublesome CNS side effects that impair their quality of life.
- **Cardiovascular response to exercise is preserved** so patients are less likely to experience the fatigue often associated with beta-blocker therapy.
- **A small percentage of patients** have experienced orthostatic hypotension and syncope.

B.I.D. Dosage Titration... the Key to Effective Control of Hypertension



BRIEF SUMMARY

MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, incontinence, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy, however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

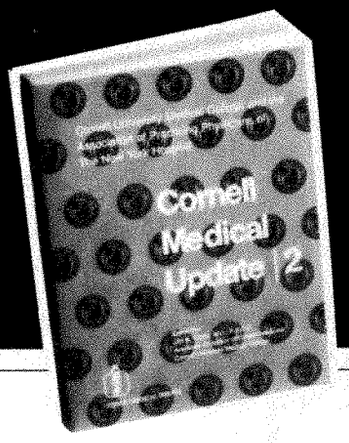
Now in book form...the latest **Update Your Medicine** lectures

Helps you keep up with the new advances in your specialty in the comfort of your home or office.



CORNELL MEDICAL UPDATE/2

Edited by LILA A. WALLIS, MD, FACP

Each of the 23 lectures is presented in a workbook format for easy reading and quick comprehension.

1. Cardiology, I: Applications of Anticoagulation; Coronary Artery Bypass Surgery; Valvular Heart Disease
2. Cardiology, II: Congenital Heart Disease in Adults, Part I
3. Cardiology, III: Congenital Heart Disease in Adults, Part II
4. Hematology: Hemostasis Made Easy
5. Gastroenterology, I: Cricoesophageal Achalasia and Gastroesophageal Reflux
6. Gastroenterology, II: Pharmacology of Acid Peptic Disease Therapy
7. Genetics, I: Basic Genetics
8. Genetics, II: Chromosomal Abnormalities
9. Genetics, III: Clinical Genetics
10. Gynecology, I: New Diagnostic Procedures and Therapy
11. Gynecology, II: New Diagnostic Procedures
12. Obstetrics: Prenatal Diagnosis of Genetic Diseases and Abnormalities
13. Infectious Diseases, I: Antimicrobial Therapy
14. Infectious Diseases, II: Virology
15. Nephrology, I: Renal Glomerular Disease
16. Nephrology: II: Management of Chronic Renal Failure
17. Ophthalmology, I: Progress in Ophthamology
18. Ophthalmology, II: Diabetic Retinopathy Vitrectomy Study
19. Psychopharmacology, I: Antipyschotic Drugs and Minor Tranquilizers
20. Psychopharmacology, II: Antidepressant Drugs
21. Pulmonary Medicine: Recent Advances
22. Rheumatology: Recent Advances
23. Calcium Metabolism: Disorders of Calcium Metabolism

All new material—specialties expanded.

The workbook format of CORNELL MEDICAL UPDATE/2 breaks medical publishing traditions by giving practitioners a quick overview of the latest advances in their specialty. It transcribes the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical Center. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice.

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 Fifth Avenue, New York, N.Y. 10103

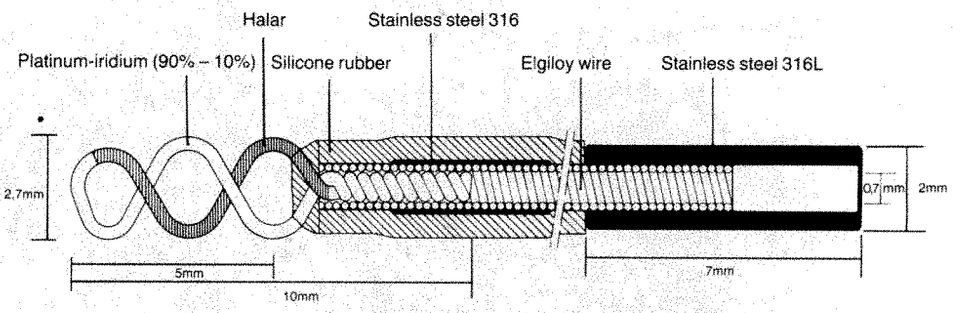
The Helifix electrode. What it can do in the ventricle, it can do in the atrium.

In the relatively short time since Vitatron first introduced Helifix* for ventricular pacing, its wide acceptance has told us something.



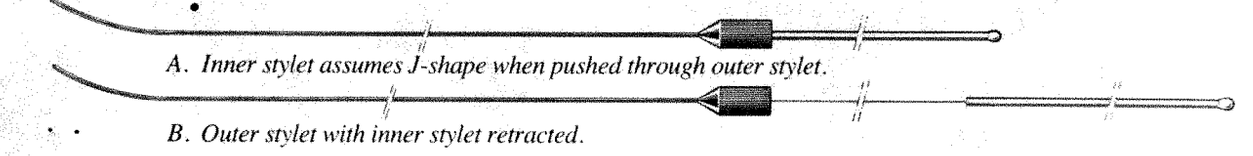
If, we reasoned, Helifix had proven so effective for ventricular pacing — 2 or 3 turns let you twist it securely into the trabeculae — it was entirely logical that it should work equally as well for atrial pacing.

And it does.

Essentially, what we've done is develop a new *double* stylet. An inner, pre-bent stylet assumes a rigid, J-shape when it's pushed through a second, outer stylet.

The result is that you can easily pull the lead upward, implanting the helical coil securely into the atrial appendage. Atraumatically. And without risk of puncturing the delicate atrial wall.

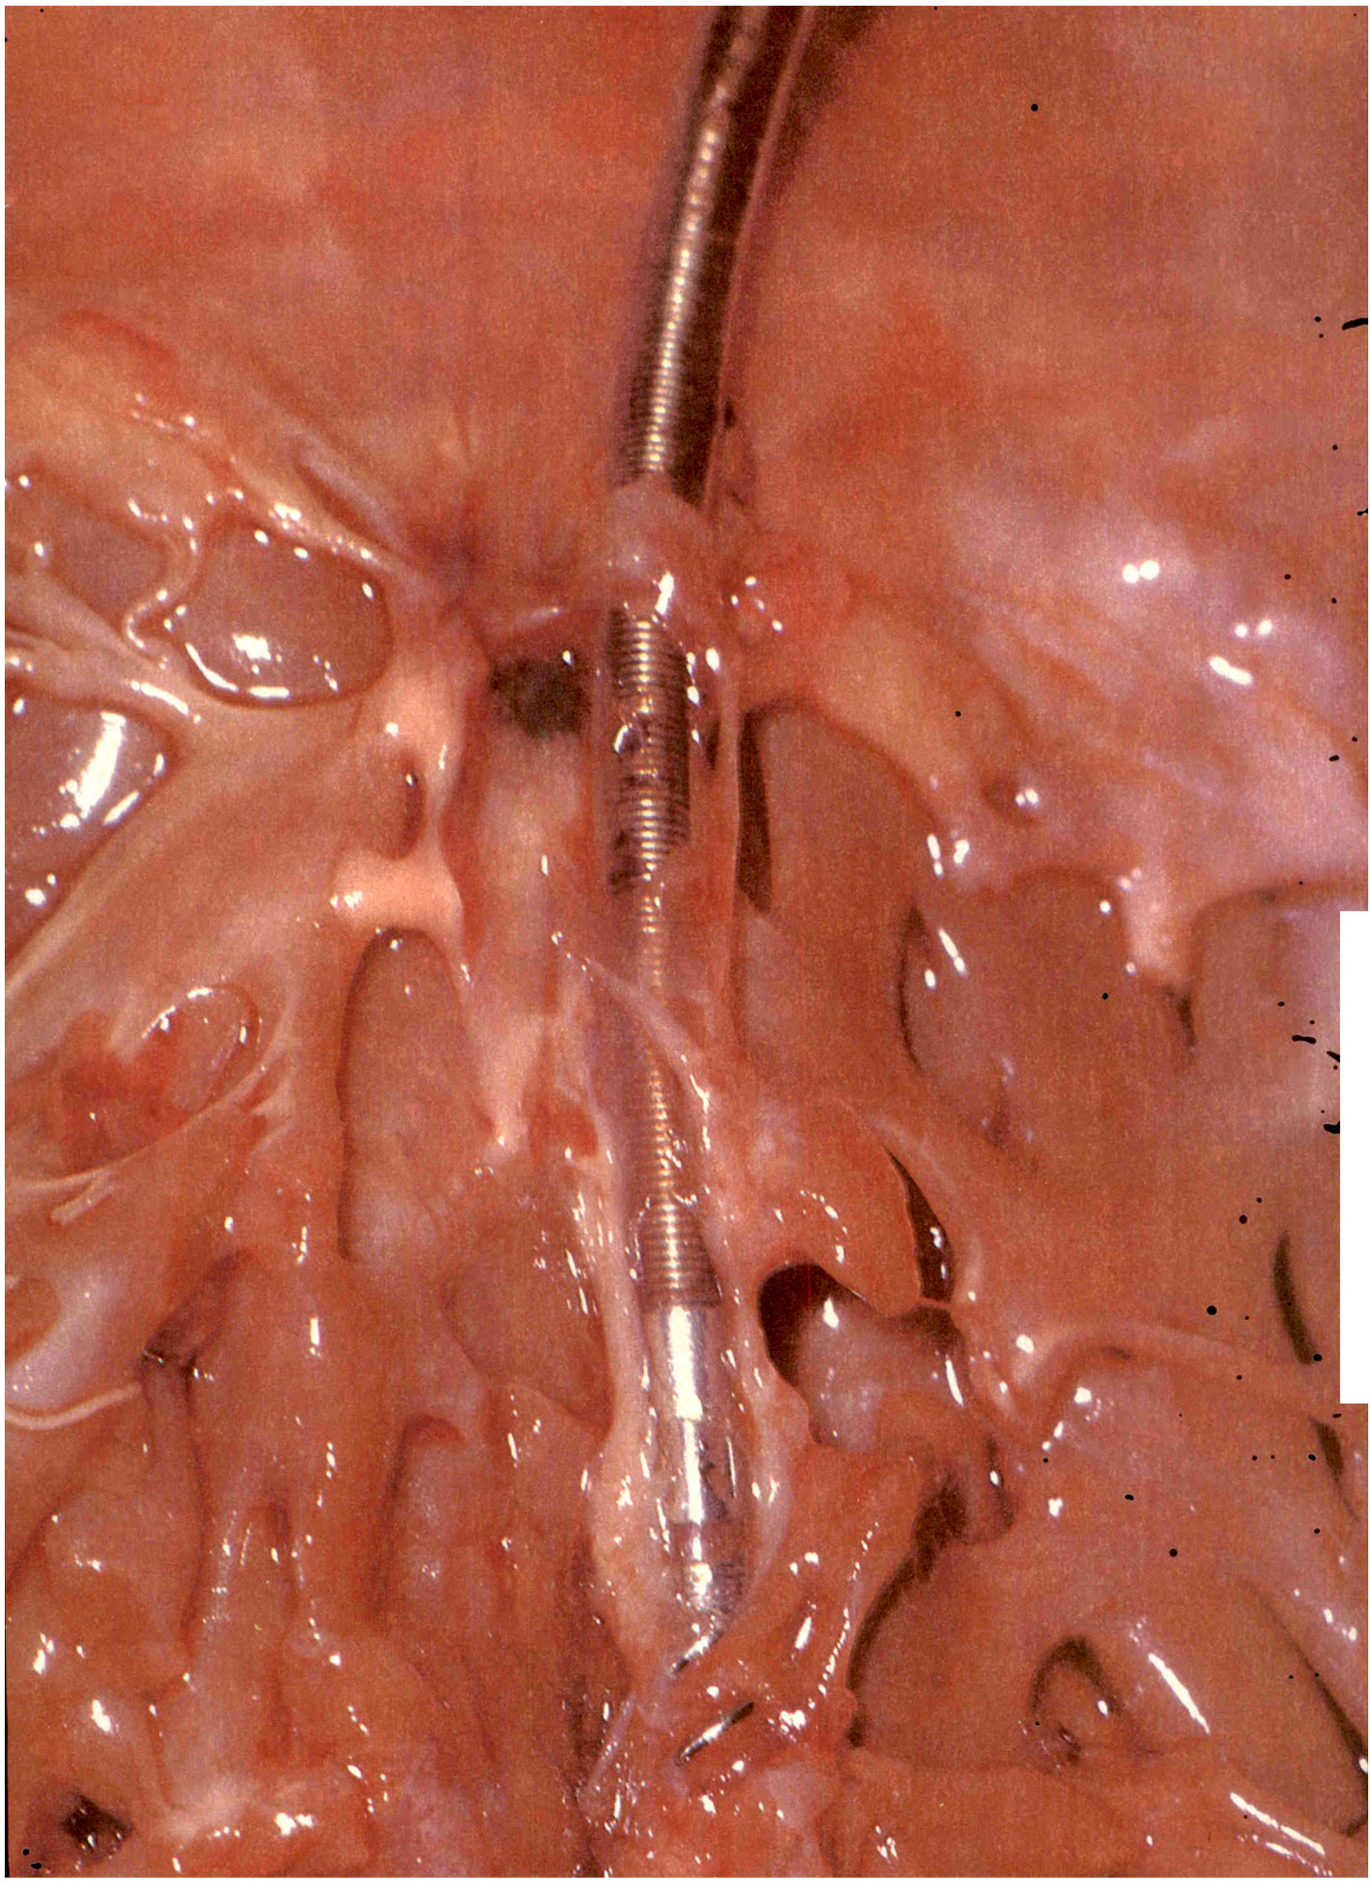
For a secure, positive solution to atrial fixation, we urge you to consider Helifix. For our latest data, including clinical evaluations, or to arrange a private screening of our new Helifix film, write: Vitatron Medical, B.V., P.O. Box 76, Dieren, The Netherlands. In the United States, call (617) 964-1980.



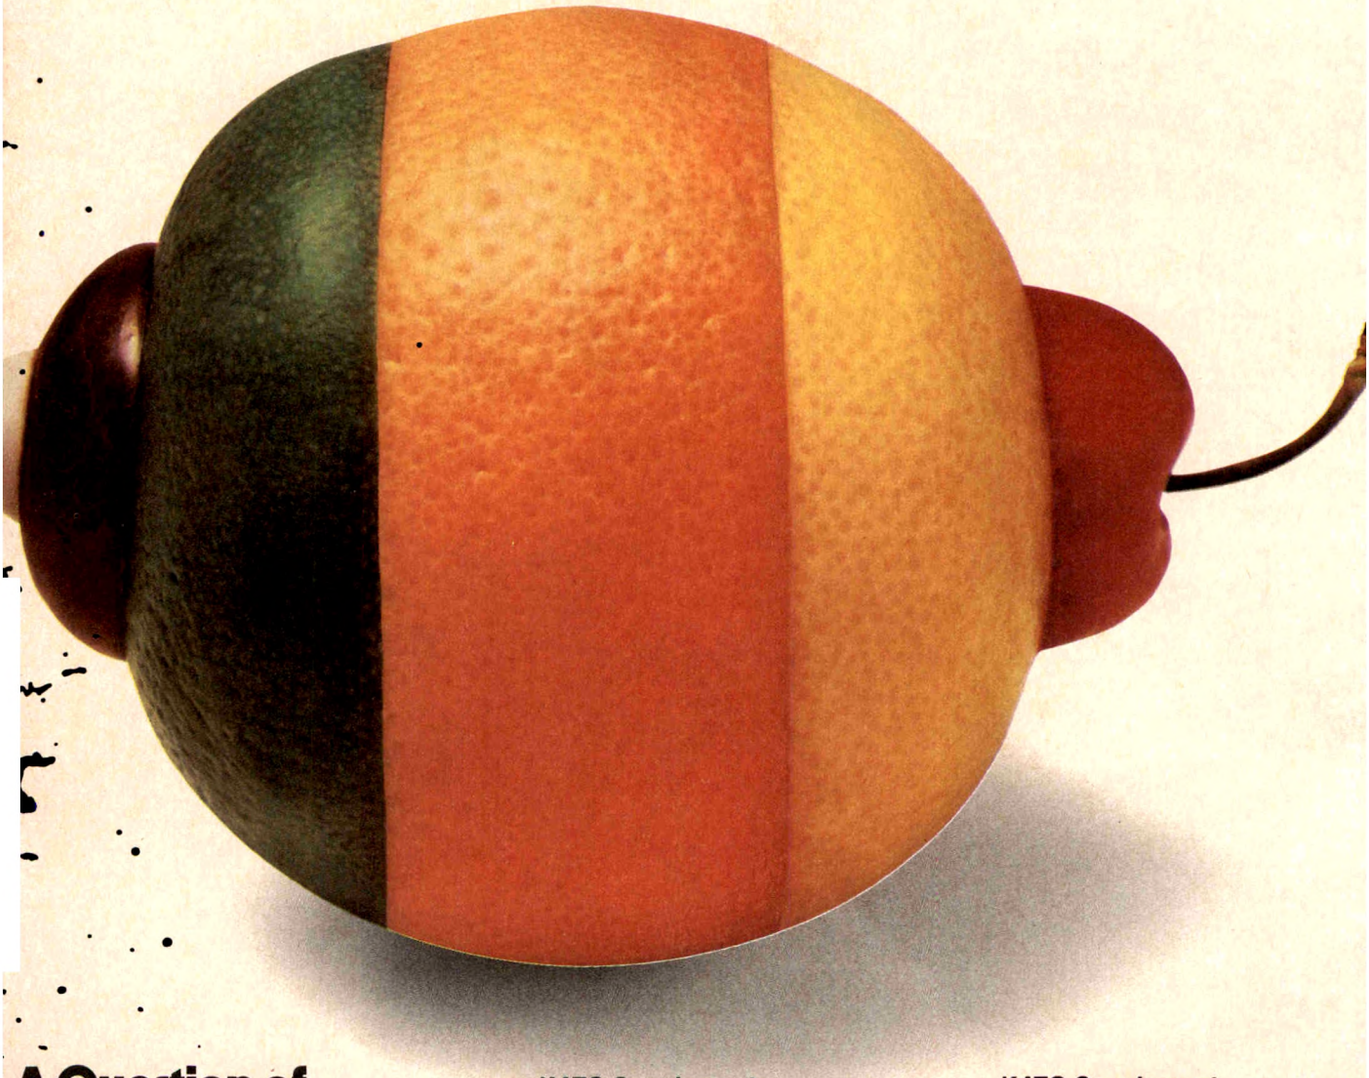
A. Inner stylet assumes J-shape when pushed through outer stylet.

B. Outer stylet with inner stylet retracted.

Vitatron Medical



Fruitless?



A Question of Compliance.

Patients on potassium supplements *won't* comply if they tire of the sweet fruity taste used to mask the "bitter pill" of potassium in their medication.
That's when a prescription for fruitless taste of KATO potassium supplement can be fruitful.

KATO Supplement. The compatible taste of tomato.

In KATO supplement, the naturally tangy taste of tomato *complements* the naturally salty taste of potassium chloride. Patients like the combination, and will stay with it day after day. Tomato-flavored KATO supplement is a natural — at breakfast and dinner.

KATO Supplement. The preferred salt in the preferred form.

Each single-dose packet of KATO supplement contains 20 mEq of potassium chloride — the preferred salt — and less than 5 mg sodium chloride. Because it contains the chloride salt, KATO supplement can be used where hypochloremic alkalosis is also a problem. KATO supplement mixes easily in water or tomato juice, and just two packets daily provide a full therapeutic dose.

Fruitful.

KATO Supplement.
It's fruitless for fruitful compliance.

- tangy, tomato taste well accepted for long-term compliance
- B.I.D. regimen encourages compliance
- liquid form minimizes potential for gastrointestinal irritation
- corrects both hypokalemia and hypochloremic alkalosis
- convenient, easy-to-carry single-dose packets

KATO®
(potassium chloride for oral solution) 20 mEq (1.5 g KCl)

SYNTEX

SYNTEX PUERTO RICO, INC.
HUMACAO, PUERTO RICO 00661

Please see prescribing information on following page.

KATO®
(potassium chloride for oral solution)
20 mEq (1.5 g KCl)

Prescribing Information

DESCRIPTION:
Spray-dried tomato powder containing 20 mEq potassium (equivalent to 1.5 g KCl) per 6 grams powder (one dose) with natural and synthetic flavors, spices and colors. Benzoic acid and potassium benzoate added as preservatives. When reconstituted as directed, makes a pleasantly flavored, low sodium tomato juice drink. Each daily dose (2 packets) contains approximately 0.5 mEq sodium.

INDICATIONS:
The prevention or correction of potassium deficit, particularly when accompanied by hypochloremic alkalosis in conjunction with thiazide diuretic therapy, in digitalis intoxication, or as the result of long-term corticosteroid therapy, low dietary intake of potassium, or excessive vomiting or diarrhea.

CONTRAINDICATIONS:
Potassium is contraindicated in severe renal impairment involving oliguria, anuria or azotemia; in untreated Addison's disease, familial periodic paralysis, acute dehydration, heat cramps, hyperkalemia from any cause. Potassium chloride should not be employed in patients receiving potassium-sparing agents such as aldosterone antagonists and triamterene.

PRECAUTIONS:
KATO is a concentrate and should be taken only after reconstituting with water as directed. This preparation, like other potassium supplements, must be properly diluted to avoid the possibility of gastrointestinal irritation. Do not use in patients with low urinary output or renal decompensation. Administer with caution; it is impossible to assess accurately the daily dose required. Excessive dosage may result in potassium intoxication. Frequent checks of the clinical status of the patient, ECG and/or plasma potassium level should be made. High plasma concentrations of potassium ion may cause death through cardiac depression, arrhythmias or arrest. Use with caution in patients with cardiac disease.

ADVERSE REACTIONS:
Vomiting, diarrhea, nausea, and abdominal discomfort may occur. Gross overdosage may produce signs and symptoms of potassium intoxication: mental confusion, listlessness, paresthesia of the extremities, weakness and heaviness of legs, flaccid paralysis, hyperkalemia, ECG abnormalities, fall in blood pressure, cardiac arrhythmias and heart block. The characteristic changes in the ECG are disappearance of the P wave, widening and slurring of QRS complex, changes of the S-T segment, tall peaked T waves, etc.

TOXICITY:
Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours.

TREATMENT OF HYPERKALEMIA:
1. Dextrose solution 10% or 25% containing 10 units of crystalline insulin per 20 g dextrose, given I.V. in a dose of 300cc to 500cc in an hour. 2. Adsorption and exchange of potassium using sodium or ammonium cycle cation exchange resin, orally or as retention enema. 3. Hemodialysis or peritoneal dialysis. 4. Elimination of potassium-containing foods and medicaments. Warning: Digitalis toxicity can be precipitated by lowering the plasma potassium concentration too rapidly in digitalized patients.

ADMINISTRATION AND DOSAGE:
Mix with water to make a pleasant tomato juice drink. Each 6-gram unit dose packet provides 20 mEq of potassium. Usual adult dose—1 packet of KATO mixed with about 2 ounces of water twice daily—supplies 40 mEq potassium per day. Take with meals or follow with ½ glass of water. Larger doses may be required, but should be administered under close supervision because of the possibility of potassium intoxication.

HOW SUPPLIED:
Cartons of 30 and 120 6-gram unit dose packets, 20 mEq each.

CAUTION:
Federal law prohibits dispensing without a prescription.

Congestive Heart Failu

Mechanisms, Evaluation and Treatmen
Dean T. Mason, M.D.

This rare treatment of such a multifaceted subject provides a portunity for the busy clinician to add to his knowledge i amount of time. Any area of immediate interest can be rapidl as much data as needed can be quickly extracted. The con improved clinical management will be appreciated by every i iologist, generalist, and any professional involved in c medicine.

Dean Mason, President of the American College of Cardic ganized this monograph within the three areas relevant to an u of congestive heart failure: *mechanisms, evaluation* and *treatr* recognized authorities have been assembled by Dr. Mason, uting their expertise to make this book the foremost text cover important and common disorders of abnormal heart function

This presentation of recent advances in basic research progress has been highly acclaimed for its major contributi provement of patient care. We invite you to see if you don't and take 30 days to look over the book. If you're not totally sa it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovasc University of California, School of Medicine, Davis.

President, American College of Cardiology; President, Western Soci Research.

Member of the American Board of Internal Medicine Cardiovascular

Has authored more than 400 original articles on cardiovascular scier cardiology.

Serves on the editorial boards of The American Journal of Cardiology, Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the Amer Pharmacology and Experimental Therapeutics, the Research Awards the American Therapeutic Society, and the Theodore and Susan Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State D the American College of Cardiology.

LOPRESSOR®

*metoprolol tartrate

exerts a relative preference for beta-one receptors.

WORKS WHERE IT SHOULD– NOT WHERE IT SHOULDN'T– IN HYPERTENSION

By concentrating its action on the beta-one receptors involved in blood pressure control and to a large extent—at usual therapeutic dosages—avoiding the unwanted effects of beta-two blockade, Lopressor offers potential benefits not available with the nonselective beta blockers.

PHARMACOLOGICAL EVIDENCE FOR SELECTIVITY...

LESS EFFECT ON PERIPHERAL CIRCULATION AFTER EXERCISE[1]
Propranolol, due to beta-two blockade, causes a greater reduction in muscle blood flow than does Lopressor.

REDUCES THE PRESSOR EFFECT OF EPINEPHRINE[2]
Propranolol augments the pressor effect of epinephrine, while Lopressor reduces the pressor effect.

BETTER TOLERABILITY IN PATIENTS WITH ASTHMA[3]
At an antihypertensive dosage (100 mg daily) there was no difference in FEV, and no patients reported any influence on their asthma.

Lopressor should be used with caution in patients with bronchospastic disease. Since beta-one selectivity is not absolute, bronchospastic patients should receive a beta-two-stimulating agent concomitantly. For complete details, see the Warnings section of the prescribing information.

Please see next page for brief summary of prescribing information.

B2

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities, arterial insufficiency, usually of the Raynaud type, palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 100 or less.

Allergic: Pruritus has occurred in less than 1 of patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia, visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added to diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. Usual maintenance dosage is approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients, especially when lower dosages are used, will experience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. If control is not adequate, a larger dose, three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

667292 C79-22 (8

Acute Effects of Ethanol on Myocardial Blood Flow in The Nonischemic and Ischemic Heart

HOWARD S. FRIEDMAN, MD, FACC

with the technical assistance of
CHARLES NEAL
ANDREW DOWD
EILEEN TAYLOR
EDWARD SHAUGHNESSY

Brooklyn, New York

To determine the effects of ethanol on myocardial blood flow in the nonischemic and ischemic heart, coronary blood flow was measured with radionuclide-tagged microspheres in the anesthetized dog before and after intravenous administration of 1.7 g/kg body weight of ethanol. In nonischemic dogs, at an average peak blood ethanol level of 225 ± 8 mg/dl (mean ± standard error of the mean), left atrial pressure increased from 5.7 ± 0.6 to 7.7 ± 0.8 mm Hg ($p < 0.01$) and heart rate slowed from 179 ± 8 to 171 ± 8 min^{-1} ($p < 0.001$) but mean aortic pressure and cardiac output were unchanged. Average myocardial blood flow increased from 122 ± 5 to 143 ± 8 ml/min per 100 g ($p < 0.001$). In dogs given ethanol after coronary occlusion, at an average peak blood ethanol level of 201 ± 13 mg/dl, left atrial pressure increased from 6.3 ± 0.6 to 7.4 ± 1.4 mm Hg ($p < 0.05$) but there was no significant change in heart rate, mean aortic pressure or peak positive first derivative of left ventricular pressure (dP/dt). In these dogs, there was a significant change ($F = 6.47$, $p < 0.001$) in the distribution of myocardial blood flow. In the nonischemic zone, blood flow increased from 118 ± 7 to 148 ± 14 ml/min per 100 g ($p < 0.005$), whereas in the ischemic zone it declined from 30 ± 6 to 20 ± 5 ml/min per 100 g ($p < 0.02$). Myocardial tissue demonstrating myocardial perfusion equal to or greater than 80 percent of preligation levels showed a significant increment of blood flow after ethanol; by contrast, myocardial tissue having blood flow levels equal to or less than 60 percent of preligation levels showed a significant decline in blood flow.

Thus, ethanol increases coronary blood flow in the nonischemic myocardium. However, in the acutely ischemic heart, ethanol produces an unfavorable redistribution of myocardial blood flow with flow in the nonischemic myocardium increasing, at least in part, at the expense of blood flow to ischemic myocardium, producing in effect a "coronary steal."

Alcohol is the oldest drug used to prevent and treat angina pectoris. Its putative benefits were first suggested by William Heberden[1] in his classic description of angina pectoris more than 200 years ago. Given the effects of ethanol on altering the perception of pain, its apparent favorable response in relieving angina pectoris might not reflect an improvement in myocardial supply-demand relations. Studies of the effect of ethanol on coronary blood flow have yielded conflicting findings. Some studies have found no change[2] or a decrease in coronary blood flow[3–5]; whereas other investigations[6–9] have demonstrated an increase. Moreover, even a demonstrable increase in total myocardial flow might not necessarily result in an increased blood supply to ischemic myocardium. Consequently, in this study we investigated the action of ethanol on myocardial flow in a canine model at blood levels of ethanol comparable with those found in man after the ingestion of several cocktails. The results indicate that, although ethanol increases blood flow to myocardium supplied by patent coronary arteries, flow to ischemic myocardium actually diminishes.

Methods

Experimental preparation: Thirty-five mongrel dogs that had fasted and weighed between 17 and 25 kg were anesthetized with sodium pentobarbital, 30 mg/kg, intravenously administered. No additional anesthesia was given during an experiment. All dogs were intubated and ventilated with a Harvard respirator. A left thoracotomy was performed and the heart was suspended in a pericardial cradle. Polyurethane catheters were positioned in the right atrium and descending aorta. Cannulas were placed in the left atrium and in the left ventricle through the apex. A Millar catheter-tipped micromanometer was positioned in the left ventricle through the apical cannula. To maintain catheter patency 4,000 units of sodium heparin was administered.

Measurements: Pressures were measured with a Statham 23dB strain gauge manometer with zero reference taken as the mid chest with the dog in a right lateral decubitus position. All pressure measurements were made over an entire respiratory cycle and the mean value of such a determination used. The first derivative of the left ventricular pressure pulse (dp/dt) obtained with the catheter-tipped micromanometer was computed continuously by a resistance-capacitance differentiating circuit and subsequently converted into mm Hg/s. The catheter-tipped micromanometer was calibrated in vivo using a fluid-filled catheter positioned in the left ventricle. Arterial pH, and partial pressures of oxygen and carbon dioxide were measured with a Radiometer Acid-Base Cart.

Myocardial blood flow was measured with 15 μ microspheres using the method of Domenech et al.[10]: Microspheres labeled with strontium-85, cerium-141, iodine-125 or chromium-51 were obtained from the 3M Company, Minneapolis in 1 millicurie vials suspended in 10 ml of 10 percent dextran, containing 0.5 percent of polysorbate (Tween 80®). After mechanical and ultrasonic agitation, 2 to 4 $\times 10^6$ microspheres were suspended in a 63 percent sucrose solution. These suspensions were agitated in an ultrasonic bath until used and then manually agitated until the moment of injection. Between 1 to 2 $\times 10^6$ microspheres in 5 ml of these suspensions were rapidly injected into the left atrium and the cannula was flushed with 5 percent dextrose in water over a 15 to 20 second period. Beginning 30 seconds before and continuing for exactly 2.5 minutes a reference blood sample was withdrawn from the arterial catheter at precisely 3.69 ml/min with a Harvard withdrawal pump. No electrocardiographic changes were observed during injection or withdrawal, and no appreciable hemodynamic alterations were produced. After the animal was killed with administration of potassium chloride, sections were obtained from the anteroapical, anterolateral and posterolateral segments of the left ventricle. Tissue was transversely divided into subepicardial, myocardial and subendocardial sections. All tissues were weighed to the nearest milligram, placed in glass tubes and counted for 5 minutes in a 3 inch (7.6 cm), well-type sodium iodide scintillation counter. Reference blood samples were divided into six aliquots. Appropriate energy windows and standard techniques were used for isotope separation.[10] To reduce further any error that might be introduced by contaminant activity contributed by accompanying isotopes and background, the order of isotopes was randomized for each experiment.

Flow to each area of myocardium (ml/min per 100 g) was calculated by using the formula:

$$QM = \frac{Qr \times Cm \times 100}{Cr \times Wt},$$

where Qm = myocardial flow (ml/min per 100 g), Qr = reference blood flow (ml/min), Cm = total counts in the myocardial sample, Cr = total counts in the reference sample and Wt = weight of the sample (g). Cardiac output (CO in liters/min) was calculated by using the formula

$$CO = \frac{Qr \times Ci \times 10^{-3}}{Cr},$$

where Ci = total counts of isotope injected. Calculation of flows was performed with an IBM Systems III computer. Ethanol blood levels were measured using the enzymatic method.[11]

Protocol: After the animals were prepared, control hemodynamic and myocardial blood flow determinations were made. In nine dogs ethanol (absolute dehydrated, USP), 1.7 g/kg body weight in a 25 percent (volume/volume) normal saline solution was continuously infused over 30 minutes. Five dogs received an equivalent volume of saline solution over the same period. Hemodynamic, myocardial blood flow and blood ethanol determinations were made after the infusion. In an additional 18 dogs, after control data were obtained, a coronary ligature was placed around the left anterior descending artery, first distal to a diagonal branch and then just proximal to the diagonal branch, as suggested by Harris et al.,[12] as a means of reducing the incidence of ventricular fibrillation. Ventricular fibrillation developed in three additional dogs. No attempt at defibrillation was made in these dogs and no antiarrhythmic agents were given to any dogs. After waiting 15 minutes for all ventricular premature complexes to disappear and hemodynamic variables to stabilize, hemodynamic and myocardial blood flow determinations were repeated. Nine dogs then received ethanol, 1.7 g/kg in saline solution delivered over 30 minutes, and nine dogs received an equivalent volume of saline solution delivered over the same period. After cessation of these infusions, hemodynamic, myocardial blood flow and blood ethanol determinations were made. The dogs were then killed with administration of potassium chloride.

Statistical analysis: Differences between groups were statistically analyzed by one way analysis of variance and Student's t test for unpaired data. Comparison of the changes in variables in the same group was performed using Student's t test for paired data. Values given are mean ± standard error of the mean. $p < 0.05$ was considered significant.

Results

Effects of Ethanol Before Coronary Ligation

Hemodynamic changes: Arterial pH, PO_2 and PCO_2 remained within physiologic limits. Only arterial pH changed after administration of ethanol, decreasing from an average of 7.41 ± 0.01 to 7.38 ± 0.01 (probability [p] <0.05). The average peak blood ethanol concentrations after 30 minutes of ethanol infusion was 225 ± 8 mg/dl (range 190 to 264) in nonischemic dogs. Ethanol produced an elevation of left atrial pressure (from 5.7 ± 0.6 to 7.7 ± 0.8 mm Hg, p <0.01) and venous pressure (from 4.1 ± 0.9 to 5.1 ± 0.8 mm Hg, p <0.01) and a slowing of heart rate (from 179 ± 8 to 171 ± 8 min^{-1}, p <0.001) (Fig. 1). Mean aortic pressure (127 ± 8 to 128 ± 9 mm Hg) and cardiac output (3.0 ± 0.2 to 2.8 ± 0.2 liters/min) (p = not significant [NS]) did not change. By contrast, an equivalent volume of saline produced no change in heart rate (160 ± 5 to 159 ± 8 min^{-1}), left atrial pressure (5.8 ± 1.3 to 6.4 ± 1.5 mm Hg), venous

pressure (5.7 ± 0.8 to 6.0 ± 0.8 mm Hg), mean aortic pressure (122 ± 9 to 118 ± 10 mm Hg) or cardiac output (2.8 ± 0.4 to 3.0 ± 0.3 liters/min).

Myocardial blood flow (Fig. 2): Average myocardial blood flow increased from 122 ± 5 to 143 ± 8 ml/min per 100 g ($p < 0.001$) after administration of ethanol. Saline solution produced no change in blood flow (117 ± 9 to 118 ± 9 ml/min per 100 g). Myocardial flow increased after ethanol in a transmural fashion. Subendocardial flow increased by 21 ± 6 from 130 ± 10 ml/min per 100 g ($p < 0.01$), myocardial flow by 24 ± 7 from 121 ± 9 ml/min per 100 g ($p < 0.02$) and subepicardial flow by 19 ± 6 from 115 ± 9 ml/min per 100 g ($p < 0.02$).

Effects of Ethanol After Coronary Ligation

Hemodynamic changes (Fig. 3): Occlusion of the left anterior descending artery produced an increase in left atrial pressure and a decrease in peak positive dP/dt. After an infusion of ethanol that produced an average peak concentration of 201 ± 13 mg/dl (168 to 288) at 30 minutes, left atrial pressure increased from 6.3 ± 0.6 to 7.4 ± 1.4 mm Hg ($p < 0.05$) but peak dP/dt declined from 2596 ± 284 to 2276 ± 257 mm Hg/s (p = NS). Heart rate (156 ± 9 to 163 ± 7 min^{-1}) and mean aortic pressure (115 ± 8 to 115 ± 6 mm Hg) did not change. By contrast, saline solution produced no change in left atrial pressure (8.6 ± 0.6 to 8.6 ± 0.7 mm Hg), heart rate (160 ± 9 to 156 ± 8 min^{-1}), mean aortic pressure (112 ± 9 to 111 ± 13 mm Hg) or peak positive dP/dt (2766 ± 339 to 2802 ± 267 mm Hg/s). Peak positive dP/dt increased in seven of the nine dogs receiving saline after coronary ligation, whereas only two of the nine dogs receiving ethanol after coronary ligation showed an improvement in this variable even though left atrial pressure had risen significantly.

Myocardial blood flow (Fig. 4): In dogs receiving saline solution, myocardial flow did not change significantly in either the ischemic (20 ± 7 to 16 ± 5 ml/min per 100 g) or nonischemic zone (122 ± 13 to 130 ± 14 ml/min per 100 g). Dogs receiving ethanol showed a significant redistribution of myocardial blood flow ($F = 6.46$, $p < 0.001$). Blood flow in the ischemic zone decreased from 30 ± 6 to 20 ± 5 ml/min per 100 g ($p < 0.02$) whereas flow in the nonischemic zone increased from 118 ± 7 to 148 ± 15 ml/min per 100 g ($p < 0.005$). Figure 5 illustrates the changes in distribution of myocardial blood flow in the ischemic heart after administration of ethanol. The decrease in blood flow is shown to occur in a transmural fashion in the ischemic zone.

In Figure 6 changes in myocardial blood flow after administration of ethanol are considered as a function of the severity of myocardial ischemia. Myocardial tissue demonstrating myocardial perfusion equal to or greater than 80 percent of preligation levels showed a significant increment in blood flow after ethanol, by 31 ± 5 ml/min per 100 g ($p < 0.001$). The increment in blood flow was greatest in the subendocardium, increasing by 42 ± 10 ml/min per 100 g ($p < 0.001$) and least in the subepicardium increasing by 17 ± 6 ml/min per 100 g ($p < 0.01$). By contrast, myocardial tissue having an average blood flow level equal to or less than 60 percent of preligation values showed a significant decline in myocardial blood flow. In myocardium with an average flow ranging between 61 to 79 percent of preligation values, subendocardium showed an increase in flow whereas the subepicardium showed a decrease in flow, by 33 ± 12 ml/min per 100 g ($p < 0.05$).

Thus, ethanol increased myocardial blood flow in a transmural fashion in the nonischemic heart. In a heart that had an acute occlusion of a coronary vessel, blood flow increased in nonischemic tissue but decreased in ischemic tissue. The increment of blood flow appeared to be greatest in the subendocardial nonischemic zone

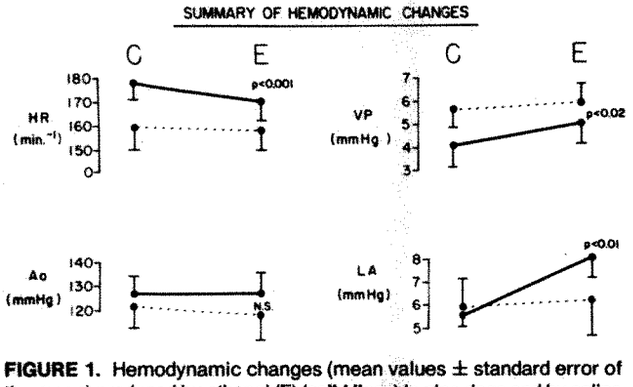

FIGURE 1. Hemodynamic changes (mean values ± standard error of the mean) produced by ethanol (E) (**solid lines**) in nine dogs and by saline solution (**interrupted lines**) in five. Ethanol produced a decrease in heart rate (HR) and an increase in venous pressure (VP) and left atrial pressure (LA) but no change in mean aortic pressure (Ao). C = control; N.S. = not significant; p = probability.

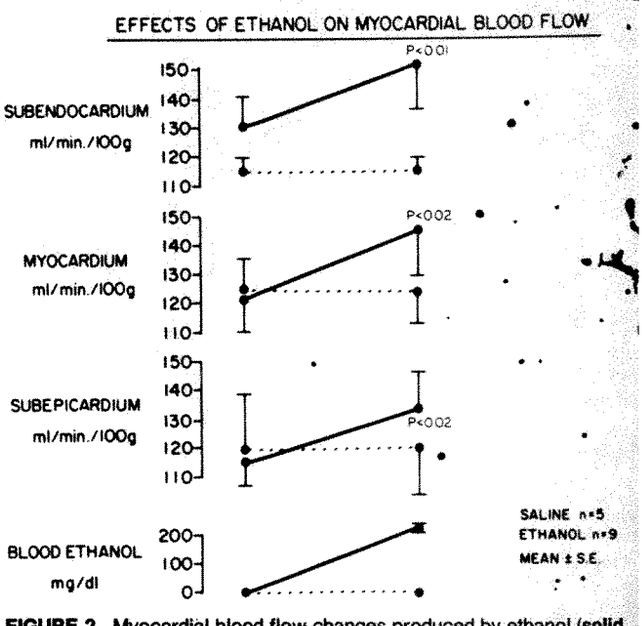

FIGURE 2. Myocardial blood flow changes produced by ethanol (**solid lines**) and saline solution (**interrupted lines**). Ethanol produced a transmural increase of blood flow whereas saline solution produced no change. n = number of studies; S.E. = standard error.

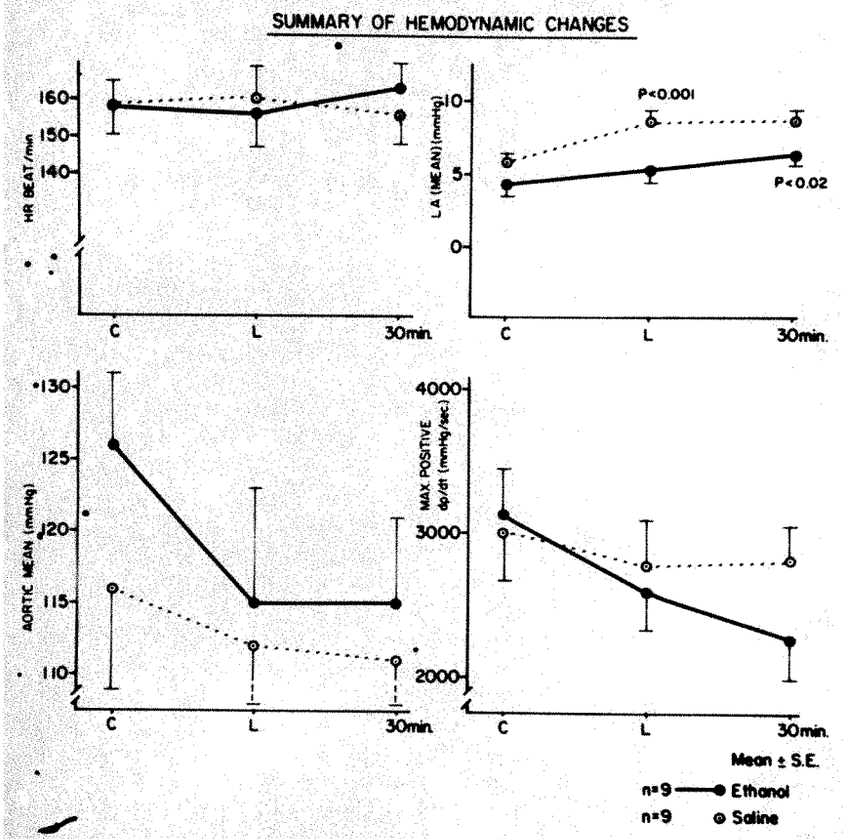

FIGURE 3. Hemodynamic changes produced by coronary arterial ligation (L) and after 30 minutes of saline or ethanol infusion. C = coated; MAX. = maximal; other abbreviations as in Figure 1.

whereas the decrease in flow appeared to be greatest in the subepicardial ischemic zone.

Discussion

Effects of ethanol on coronary blood flow: Within physiologic limits in the intact heart, the coronary circulation is autoregulatory.[13] Because ethanol has a complex array of hemodynamic and metabolic effects, it should not be surprising that conflicting observations have been made on the effects of ethanol on myocardial blood flow. Ethanol[6] and its metabolite, acetaldehyde,[14] both have direct coronary vasodilatory effects. The depressant actions of ethanol[5,9,15] and the catecholamine-releasing properties of both ethanol[16] and acetaldehyde[17] can also produce changes in myocardial blood flow by affecting myocardial oxygen consumption. Previous studies have differed in the animals used, the dosage or rate (or both) of ethanol administration, the types of anesthesia and also the methods used for measuring changes in coronary blood flow. Given these

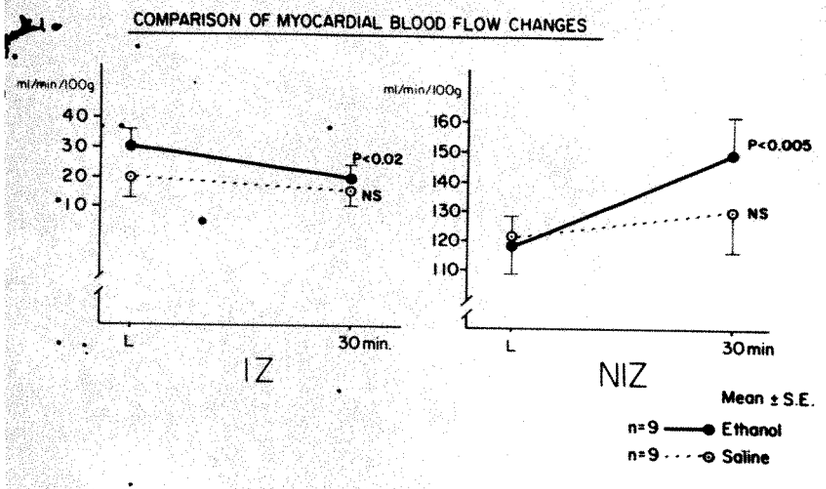

FIGURE 4. Myocardial blood changes produced by ethanol and saline solution in ischemic zone (IZ) and nonischemic zone (NIZ) of myocardium. Ethanol (**solid line**) reduced flow in ischemic tissue and increased flow in nonischemic tissue. Saline solution (**broken line**) did not produce a significant change.

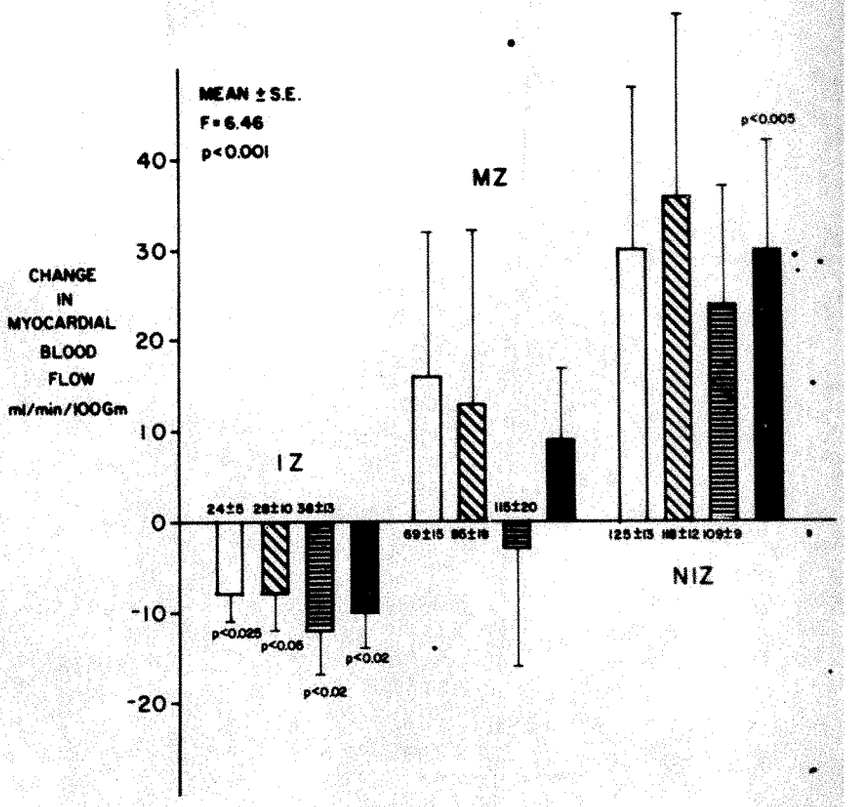

FIGURE 5. Redistribution of blood flow produced by ethanol. Ischemic (IZ), adjacent to ischemic (MZ) and nonischemic (NIZ) zones, and subendocardial (**white bars**), myocardial (**diagonal lines**), subepicardial (**horizontal lines**) and average transmural (**black bars**) flows are compared. **Values at base of bars** indicate myocardial flow after coronary ligation; **bars** indicate changes produced by ethanol.

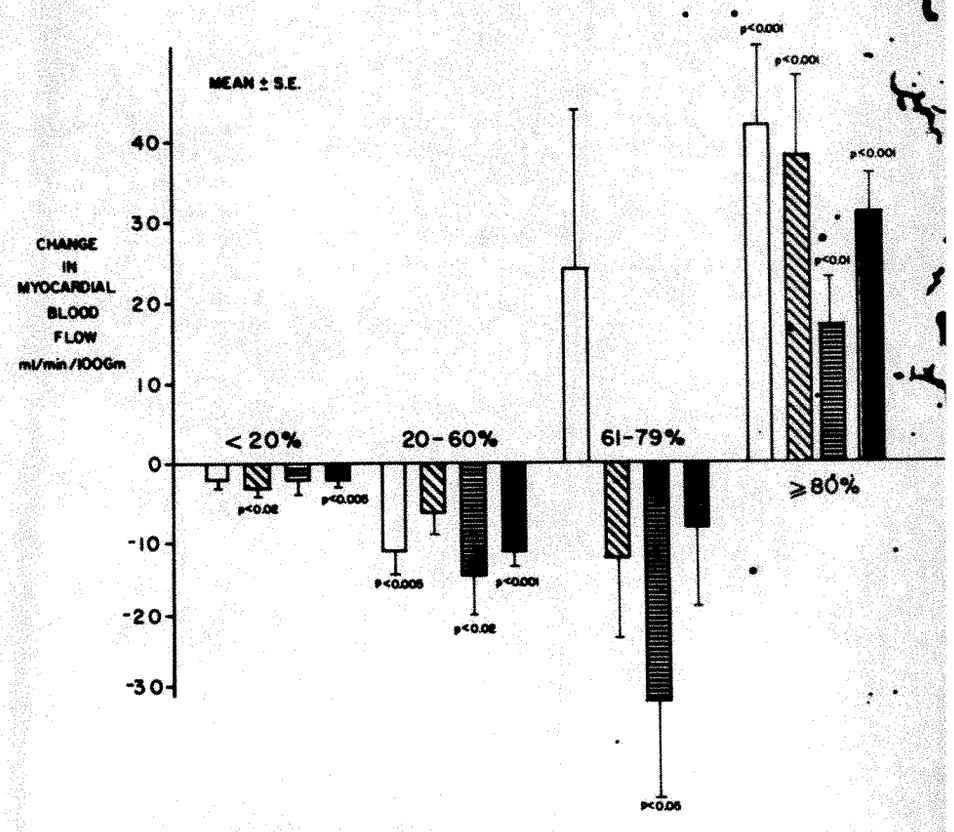

FIGURE 6. Effect of ethanol on myocardial blood flow displayed as a function of tissue flow (expressed as a percent of preligation flow before ethanol administration). Subendocardial (**white bars**), myocardial (**diagonal lines**), subepicardial (**horizontal lines**) and average transmural (**black bars**) flows are compared.

differences, some investigators[6–9] reported an increase in coronary flow after ethanol administration, some[3–5] found a decrease, others[2] observed no change, and one group[18] found no change at a low blood level of ethanol but an increase in blood flow at concentrations approximating the levels found in our study.

In our study, at blood levels that would produce alcoholic intoxication in man, ethanol was shown to increase myocardial blood flow in the neurally intact anesthetized dog. In these experiments an increase in flow occurred at a time when mean aortic pressure and cardiac output had not changed, left atrial pressure had increased and heart rate had slowed. Although myocardial oxygen consumption and coronary sinus oxygen content were not measured, in a series of similar experiments[9] that produced comparable hemodynamic effects but a more variable response on heart rate and left atrial pressure, myocardial oxygen consumption and coronary venous oxygen levels were found to increase after ethanol administration.

Ethanol and myocardial blood flow in ischemic versus nonischemic myocardium: Because a substance that increases total coronary blood flow might not necessarily result in an increase in blood flow to ischemic myocardium under similar experimental conditions, the effects of ethanol on myocardial flow after coronary ligation were studied. Although blood flow in nonischemic myocardium increased following ethanol administration, in the ischemic myocardium it declined. The decline in perfusion was observed in myocardium having an average blood flow equal to or less than 60 percent of preligation levels. Blood flow declined in a transmural fashion in the ischemic myocardium. However, the pattern of flow in nonischemic areas suggested that the maximal increment of flow occurred in the subendocardium whereas the maximal decrease occurred in the subepicardium. Thus, ethanol appears to produce an unfavorable redistribution of blood flow in the ischemic heart, with blood flow increasing in nonischemic myocardium, in part at least, at the expense of flow to ischemic myocardium, in effect producing a "coronary steal."

Potential limitations of study: Our observations must be viewed in the context of the experimental design. One limitation is that the dogs were studied after they had been anesthetized with sodium pentobarbital. However, in a study of conscious dogs ethanol was found to increase coronary blood flow.[8] It would thus seem plausible to adduce from our data that ethanol is likely to produce a "coronary steal" in the conscious dog after coronary ligation. A second limitation of the study is that ethanol was infused intravenously rather than imbibed. The failure of a saline infusion to produce the changes observed would argue in favor of ethanol or its metabolite, or both, as the agent responsible for the changes observed rather than the saline solution or the volume administered itself. Furthermore, measurement of acetaldehyde levels during ethanol infusion under similar experimental conditions[9] demonstrated that ethanol is metabolized in the dog in a similar fashion to that observed in human beings given an infusion of ethanol.[19]

A third concern is the canine response to an acute coronary ligation. In dogs, unlike human beings, coronary collateral vessels rapidly develop after an acute coronary ligation. Because most of these vessels appear within a few minutes after ligation[20], we attempted to mitigate the effects of this response by allowing 15 minutes to elapse before obtaining control data. Also, the effect of ethanol on perfusion to ischemic myocardium resulting from an acute occlusion might be different from the effect of ethanol on myocardial ischemia due to coronary stenosis with superimposed coronary spasm. Finally, the blood levels of ethanol obtained in our study, while within the range observed in human beings with acute alcohol intoxication, are in excess of those that would be seen with more casual use of alcoholic beverages. It is possible that smaller quantities ingested and producing lower blood levels might have had different effects on the ischemic myocardium.

Clinical significance: This study suggests another possible adverse effect of ethanol in organic heart disease. It has previously been shown that ethanol depresses cardiac function in patients with heart failure.[21] Ethanol may also adversely affect myocardial demand-supply relations in ischemic myocardium. Clinical studies[23] have demonstrated that angina pectoris and the abnormal electrocardiographic response to exercise are not favorably affected by ingestion of alcohol[22] and that myocardial ischemia might even occur sooner and with more exaggerated S-T segment depression. Moreover, a toxic myocardial infarction has been described in alcoholic patients not having coronary heart disease.[24] It is possible that a "coronary steal" produced by ethanol might contribute to these occurrences. Although several epidemiologic surveys[25–27] suggest that ethanol may have a protective effect on atherogenesis, our study suggests that ethanol ingestion should at least be limited in patients with coronary heart disease.

Derivation of Systolic Time Intervals From Doppler Measurement of Temporal Arterial Blood Flow

JAMES A. ROTHENDLER, MD
EDGAR C. SCHICK, Jr., MD
THOMAS J. RYAN, MD, FACC

Boston, Massachusetts

The carotid pulse method of recording systolic time intervals is limited by significant motion-induced artifact, making it unsuitable for studying patients during exercise. As an approach to overcoming this limitation, a new method utilizing the blood velocity profile of the superficial temporal artery measured by Doppler ultrasound has been developed. When compared with the values obtained from the conventional carotid pulse method, Doppler-derived left ventricular ejection time and preejection period showed excellent correlation (r = 0.99 for both) and the Doppler-derived measurements showed little intra- or interobserver variability. Studies performed during treadmill exercise showed that in 8 of 10 subjects, suitable tracings could be recorded through stage 3 of the Bruce protocol, confirming the enhanced stability of the technique compared with the carotid pulse method.

Over the past decade, systolic time intervals have frequently been used as an approach to the noninvasive evaluation of left ventricular function.[1–13] The carotid pulse tracing has traditionally been the basis for determination of left ventricular ejection time and the preejection period. However, the unstable relation of the transducer to the underlying carotid artery is a significant limitation of this technique; even minor movement of the neck muscles can introduce considerable artifact into the tracings. As a result, the diagnostic application of systolic time intervals to the evaluation of left ventricular responses during physical exertion has been difficult using the carotid pulse method.

In an effort to overcome this limitation, we developed a new method of deriving systolic time intervals, by utilizing the blood flow profile of the superficial temporal artery as measured with Doppler ultrasound. This report outlines our initial experience with the technique.

Methods

Recording technique: A commercially available Doppler flow probe (Parks Electronics, Beaverton, Oregon) consisting of miniature transmitting and receiving crystals embedded in a 1.5 by 2 cm flat plastic housing (Fig. 1, top) was used to generate a velocity profile suitable for derivation of systolic time intervals. One crystal transmits an ultrasonic wave (9.7 megahertz) that is reflected from moving red blood cells; the reflected signal is frequency-shifted in direct proportion to the blood flow velocity and is received by the second crystal for further processing. The transducer is positioned by palpating the superficial temporal arterial pulse over which the transducer is then placed (Fig. 1, bottom), oriented with the groove on the transducer surface immediately over the artery and parallel to its course to minimize arterial compression. The transducer is next secured in place with an elastic headband; final positioning is accomplished with the aid of audio and visual oscilloscopic feedback to insure an optimal flow tracing.

The transducer is interfaced with a continuous wave Doppler flowmeter (Parks Electronics model 806) that detects the magnitude and direction of the frequency shift of the signal reflected from moving red blood cells and electrically transforms these data into a voltage proportional to blood flow velocity that is then displayed on an oscilloscopic recorder for permanent copy. Calibration of ab-

solute velocity was not employed because relative changes in velocity were sufficient for purposes of this study.

To validate systolic intervals derived by this technique, we obtained simultaneous recordings of the ipsilateral carotid pulse employing an air-coupled Statham P23Db transducer. A phonocardiogram was obtained with a contact microphone (Cambridge 3040500) positioned to optimize recording of the aortic component of the second heart sound. Carotid systolic time intervals, preejection period and left ventricular ejection time were derived by the method of Weissler et al.[1] For consistency, the right temporal artery and right carotid pulse tracings were compared in all cases.

Study subjects: Twenty normal subjects aged 21 to 35 years were studied using these techniques in the supine position; 10 were also studied while sitting, standing and standing immediately after completion of treadmill exercise. We also applied this method to 10 normal volunteers exercising through stage 3 of the Bruce protocol. Reported values are an average of systolic time interval determinations from five measured beats. The results of carotid and temporal arterial Doppler systolic time intervals were compared using linear regression analysis.

Results

Comparison of Doppler and carotid pulse method: The temporal arterial velocity profile demonstrates a discrete point of upstroke and a sharp incisura (Fig. 2) analagous to the carotid waveform but with a longer pulse transmission delay. Left ventricular ejection time was determined as the interval in milliseconds from the point of rapid upstroke to the incisura. The preejection period was then derived by subtracting the left ventricular ejection time from the interval Q-A_2 (Q wave to aortic component of second heart sound).

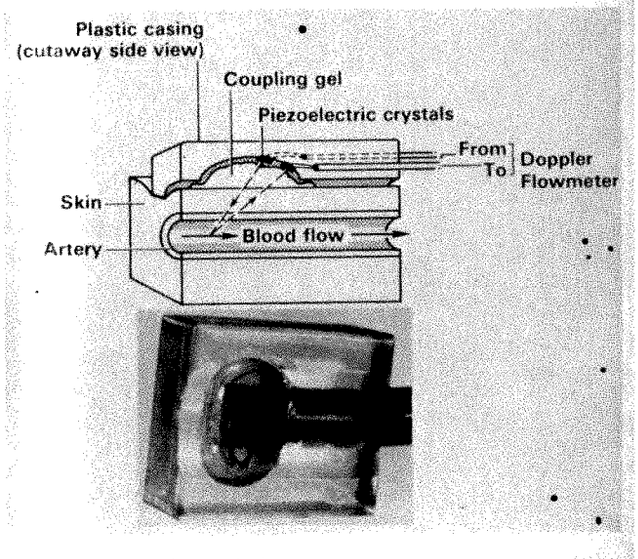
When compared with the values obtained from the conventional carotid pulse method, Doppler-derived left ventricular ejection time (LVET) and preejection period (PEP) demonstrated excellent correlation (Fig. 3) with regression equations as follows:

$$LVET_D = 0.98\ LVET_c + 4.9\ (r = 0.99)$$

$$PEP_D = 1.05\ PEP_c - 5.4\ (r = 0.99)$$

where D = Doppler and c = carotid method. The maximal difference between left ventricular ejection time measured with the Doppler and carotid methods for any individual patient was 10 ms, with a mean absolute difference of 2.9 ms (standard deviation 2.4 ms). As a result of the effects of the different positions used on systolic time intervals, a wide range of values for both the left ventricular ejection time and the preejection period was available for comparison.

Reproducibility of Doppler determinations: To assess the reproducibility of Doppler determinations of the left ventricular ejection time, duplicate measurements were made on the tracings of 12 subjects studied in the supine position. Interobserver variability was determined by having a second observer measure the left ventricular ejection time from the same tracings used for the initial data without constraint regarding complexes chosen for the measurement. Intraobserver variability was assessed by having one observer record systolic time intervals from the same tracings in each of the 12 subjects on two different occasions. The data were then compared using the t test and linear regression analysis. For interobserver data, the mean difference in left ventricular ejection time was 1.4 ms (range 0 to 7, standard deviation 3.7) with a correlation coefficient of 0.98. For intraobserver data, the mean difference was 0.2 ms (range 0 to 5, standard deviation 2.8) with a correlation coefficient of 0.99. In neither case was the difference between measurements statistically significant by the t test ($p > 0.1$).



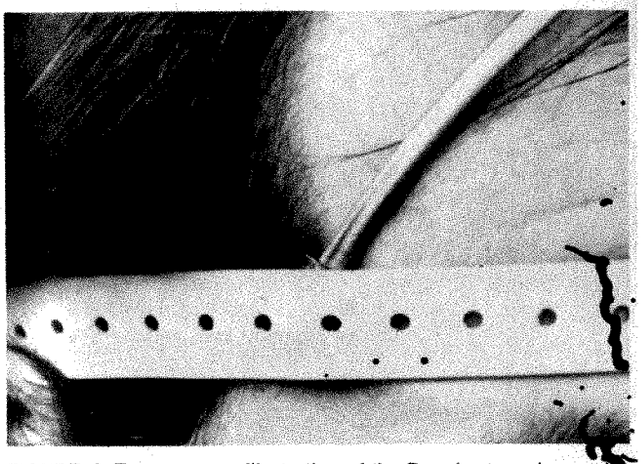


FIGURE 1. Top, cutaway illustration of the Doppler transducer with close-up view of the actual transducer. **Bottom,** close-up photograph of a subject with the transducer positioned over the temporal artery and secured with the elastic headband.

In studies conducted during treadmill exercise, tracings of 8 of the 10 subjects were suitable for measurement through stage 3 of the Bruce protocol. Figure 4 is a representative tracing of temporal arterial Doppler flow velocity obtained from one subject during stage 3 at a heart rate of 145 beats/min. The sharp upstroke and incisura remain easily identifiable at this point.

Discussion

Recording of the carotid pulse wave for the derivation of external systolic time intervals is somewhat restricted in application by cervical anatomy. The overlying soft tissue and muscle occasionally prevent acquisition of

a suitable tracing, and significant activity of the neck musculature such as that seen with respiratory distress or exercise has significantly limited application of systolic time intervals in these situations. For example, most previously reported responses of systolic time intervals to exercise have compared values obtained before and after (but not during) exercise or, if done during exercise, have generally been limited to healthy young persons studied in the supine position.[2,3,5–11,13] Alternative techniques have been described, including finger plethysmography, ear densitometry and impedance cardiography,[14,16] but each of these methods has the drawback of requiring either extrapolation or further electronic processing (usually differentiation) of the raw signals to identify the timing of the aortic incisura. The impedance cardiogram was found by Balasubramanian et al.[16] to be unsuitable for use in treadmill exercise and in all but mild sitting bicycle exercise because of motion-induced artifact.

Correlation of systolic time intervals derived by temporal arterial velocity and conventional carotid methods: Velocity curves in previous reports[17,18] relating to blood flow and acceleration in the aorta suggested that the velocity profile might provide the nec-

essary information for derivation of left ventricular ejection time. We chose the superficial temporal artery because it is easily accessible, does not vary in its relation to overlying tissues and seemed unlikely to be subject to muscle contraction artifact. Our results demonstrated that the velocity profile of this artery may be used as an accurate basis for calculating systolic time intervals, the results correlating highly with values obtained by the conventional carotid method.

Requisite to this correlation is a similar relation between the pulse transmission times: $upstroke_{carotid}$ to $upstroke_{Doppler}$ and $incisura_{carotid}$ to $incisura_{Doppler}$. Any difference in these intervals would result in a difference of calculated ejection times, which may be expressed as

$$LVET_D - LVET_c = \Delta t_i - \Delta t_u,$$

where c = carotid method; D = Doppler method; Δt_i = interval between incisuras; Δt_u = interval between upstrokes; and LVET = left ventricular ejection time. Despite the high correlation coefficient and the small mean absolute difference in ejection time, the regression equation implies that some systematic difference may exist. To estimate the magnitude of such a difference (either constant or as a function of ejection time) over the range studied, direct substitution of sample values may be made in the regression equation. For a carotid-derived ejection time of 180 ms (the lower end of the range studied), the calculated value for the Doppler-derived ejection time would be 181.3 ms. For a carotid-derived value of 330 ms (the upper end of the range studied), the Doppler-derived value would be 328.3 ms. Therefore, there may be some systematic difference between the two methods, in that the Doppler-derived value is slightly greater for very short ejection times, whereas the carotid-derived value is slightly larger for longer ejection times. (This would imply that the pulse transmission time between incisuras is slightly greater than that for the upstrokes for short ejection times and smaller for very long ejection times.) However, the estimated difference in the range studied is very small and probably within the range of measurement error for carotid-derived ejection time.[19]

Advantages of the method: The major advantage of this new technique is reduction in motion artifact as demonstrated by our ability to record satisfactory tracings in 8 of 10 subjects exercising through stage III of the Bruce treadmill protocol. (In contrast, we were unable to record systolic time intervals using the carotid pulse method during stage I of the Bruce protocol.) The specific source of the artifact that obscured the upstroke and incisural points in two of our subjects (and affected others to a lesser extent) is not entirely clear. Apart from the obvious possibility of motion of the transducer itself, it is likely that the up and down motion of the body during running causes an acceleration and deceleration of the column of blood in the aorta that is superimposed on the aortic blood velocity and transmitted to the temporal blood flow as well. Beyond stage III of the Bruce protocol, most subjects must run, and the exaggerated "bobbing" motion makes even this method impractical. In practice, this may not be an important limitation in the testing of patients. For example, more than 80 percent of patients in our laboratory found to have significant coronary artery disease on cardiac catheterization studies are not able to exercise beyond stage III. The technique is simple and the flow curves provide discrete points for measurement, thus averting the need for extrapolation or further processing. This method could easily be adopted by any laboratory with Doppler vascular blood flow equipment. Recent work

by Goldwater et al.[20] supports the accuracy of this technique in studying patients under a variety of conditions affecting ejection time.

Future applications: Another aspect of this technique, which awaits further evaluation, is the potential for use of the additional information provided by the velocity profile. Ejection velocity and acceleration data permit more complete characterization of ventricular function than systolic time intervals alone. Previous studies employing both invasive and noninvasive techniques[17,18,21–27] have shown flow indexes in the aorta and more peripheral vessels to be useful in characterizing left ventricular function and evaluating valvular heart disease. Further experience and correlative studies will be necessary to define completely the usefulness of this technique in such applications.

Predicting Cardiac Morbidity Based on Risk Factors and Coronary Angiographic Findings

JOEL E. DIMSDALE, MD
JOHN GILBERT, PhD*
ADOLPH M. HUTTER, Jr., MD, FACC
THOMAS P. HACKETT, MD
PETER C. BLOCK, MD, FACC

Boston, Massachusetts

A cohort of 189 men was followed up for 1 year after performance of coronary angiography and determination of risk factors to ascertain which risk factors or clinical and laboratory findings could aid in predicting the patients who would have a substantial cardiac morbid event. Data on clinical signs and symptoms, psychosocial assessments, angiographic findings and presence of standard risk factors for coronary artery disease were collected in each case.

Twenty-five percent of the men experienced a substantial cardiac morbid event (hospitalization, myocardial infarction, resuscitation or death). With or without inclusion of the patients who underwent surgery, discriminant analysis equations were successful in predicting morbidity on the basis of risk factor data. For the whole sample such analysis was significant at $p < 0.00005$ and accurately predicted the fate of 78 percent of the subjects. With exclusion of the surgically treated patients, the discriminant analysis accurately predicted future morbidity 83 percent of the time ($p < 0.0001$). The following risk factors for increased morbidity were common to both analyses: severity of angina, history of myocardial infarction, family history of heart disease, fatigue and absence of type A behavior.

In addition to diagnosis, cure or palliation, patients often see physicians for an assessment of their prognosis. However, the estimation of prognosis in ischemic heart disease is a complicated matter wherein many factors must be considered. Changes in medical or surgical treatment, advances in the knowledge of factors conveying risk for illness, advances in understanding the pathophysiology of these risk factors, as well as the patient's life style and unknown factors complicate any effort to prognosticate accurately.

In earlier work we[1–4] reported our efforts to utilize a broad range of risk factors for coronary artery disease to assess their relation to the extent of such disease found on angiography. This study extends the findings of our earlier work by examining prospectively the subsequent development of cardiac morbid events in patients who have undergone careful risk factor determination and coronary angiography. A cohort of patients was followed up for 1 year to ascertain which risk factors or clinical and laboratory findings could aid in predicting the onset of later morbidity. Factors ranging from clinical observations on the patient's physical examination to data from laboratory studies, psychometric tests and interviews and, finally, coronary angiography were included in each person's assessment. Although some excellent studies[5,6] have related various individual risk factors and combinations to the later incidence of morbid events, we believe that this broad-based approach may provide additional information.

Method

Study patients: Patients were eligible for study who underwent cardiac catheterization primarily because of symptoms of coronary artery disease. Men between the ages of 18 and 70 years were included in this study; the average age

was 50 years. Patients were excluded from the study if they underwent angiography for valvular heart disease, had any severe illness other than heart disease that might influence their clinical course during the follow-up period, or were in such critical condition that interviews were not feasible.

In a 2 year period, 216 men were approached for enrollment in this study. Only 12 did not participate—3 because the primary physician advised against participation, 6 because the patient himself declined to participate and 3 because they were found ineligible; thus, 204 men were studied.

Risk factors studied: Table I lists the risk factors studied. Information on these factors was obtained before angiography through patient interviews and chart reviews. Tension, depression, anger and fatigue were measured with the Profile of Mood States.[7] Denial was measured with the Hackett-Cassem semistructured interview.[8] Type A personality was measured with the Jenkins Activity Survey (JAS).[9] Stress accumulation was measured with a 42 item Schedule of Recent Events (SRE).[10] The patient was considered to have a family history of heart disease if a parent or sibling had had heart disease before age 60 years. Diabetes was considered present if the patient had been treated with an antidiabetic agent; it was considered possibly present if he had a history of an abnormal glucose tolerance test or had been told by a physician that he needed to be on an antidiabetic diet. Smoking was measured in pack-years. Electrocardiograms were graded as normal or abnormal using the criteria of Peel et al.[11]; Q waves were scored as present or absent. Severity of angina was graded according to New York Heart Association criteria.[12] Cholesterol and triglyceride values were measured as fasting levels. The Coronary Prognostic Index was derived by the method of Peel et al.[11]

Coronary angiography: The majority of patients underwent angiography at a time remote from myocardial infarction. Cardiac catheterization was performed by the Judkins or Sones technique. Vessels were considered significantly narrowed if they showed 50 percent or greater narrowing of diameter. Vessel disease was graded from 0 (no significant vessel disease) to 4 (significant vessel disease in the left main coronary, left anterior descending, left circumflex and right coronary arteries). Angiography was performed and X-ray films interpreted by physicians unaware of the risk factor determinations for this research. Although all patients were presumed to have coronary artery disease, approximately 15 percent were found to be free of any major coronary artery disease on angiography.

Follow-up: Follow-up contact was attempted 1 year after coronary angiography. Follow-up interviews were conducted either in person or by telephone; if the patient had moved out of the country, information was gathered from written questionnaires. One hundred eighty-nine of the 204 patients or their families were contacted and completed the follow-up interview. Seventy-nine men underwent coronary bypass surgery in the follow-up period. Because of the possibility that surgical treatment would alter the relation between incoming risk factors and the developing morbidity, the data were analyzed in two ways— (1) considering the total population of 189 men, and (2) considering only the 110 nonsurgically treated men.

Morbid events were classified as follows: No morbid event, emergency room visit because of cardiac problem, hospital admission because of cardiac problem, myocardial infarction, resuscitation or death. If bypass graft surgery was performed within 4 months of angiography, the hospitalization for surgery was not counted as a morbid event. It is our impression that bypass surgery performed later than 4 months after angiography is usually motivated by a deterioration in the patient's condition; in such cases hospitalization was counted as a morbid event. Table II lists the morbid event experience accumulated by our cohort. Each patient was assigned a morbidity category corresponding to the worst morbid event occurring in the 1 year follow-up period. Thus, a patient who had two emergency room visits and one hospitalization was assigned a morbidity score corresponding to a hospitalization. In an effort to maximize the amount of agreement about what constitutes a "morbid event," emergency room visits were not considered "substantial morbid events." Approximately 25 percent of the sample accrued a substantial morbid event (worse than an emergency room visit) in the follow-up period.

Statistical analysis: The association of the later development of morbidity with combinations of earlier determined risk factors and angiographic findings was examined with discriminant analysis.[13] This statistical procedure utilizes as few variables as possible and weights them to derive the optimal polynomial equation that separates subjects into two distinct groups. In this case the two groups were: (1) patients who accumulated a substantial morbid event, or (2) patients who accumulated no morbid event other than emergency room visits. By considering the interaction between variables, this technique pares the list to an optimal combination of variables predictive of who would have a substantial morbid event.

TABLE I

Risk Factors Considered

Angiographic extent of coronary artery disease
Serum cholesterol
Serum triglyceride
Depression
Anger
Fatigue
Type A behavior
Denial
Stress
Abnormal electrocardiogram
Diabetes
Family history of heart disease
Severity of angina
Q waves on electrocardiography
Tension
Peel score
History of past myocardial infarction
Blood pressure
Age
Smoking

TABLE II

Morbid Events Accumulated in 1 Year by All Cohort Patients*

	Cases	
	n	%
No morbid event	126	(66)
Emergency room visit for cardiac problem	15	(8)
Hospitalization for cardiac problem	30	(16)
Myocardial infarction	9	(5)
Resuscitation	2	(1)
Death	8	(4)

* Each patient is classified according to his most serious morbid event.

Results

We used a stepwise discriminant analysis to search for the optimal combination of variables listed in Table I that would differentiate between patients experiencing a substantial morbid event and patients without a substantial morbid event. Table III summarizes these findings. For the whole group the discriminant analysis was highly significant ($p < 0.00005$), accurately predicting the fate of 78 percent of the men. The most important variables (in decreasing order of importance) were: severity of angina, history of past myocardial infarction, family history of heart disease, fatigue, absence of type A personality, depression and a low serum cholesterol level.

After exclusion of the surgically treated patients, discriminant analysis was still highly significant ($p < .0001$), accurately predicting the fate of 83 percent of the men. The most important variables (in decreasing order of importance) were severity of angina, history of past myocardial infarction, family history of heart disease, presence of electrocardiographic Q waves, age, stress, absence of type A personality, low level of acknowledgment of anger, and fatigue. The number of coronary vessels found diseased on angiography was not a discriminating variable for either of the two equations.

Discussion

Limitations and advantages of study: This is a small sample from a highly selected group—patients undergoing coronary angiography at a university teaching hospital. These limitations must be kept in mind before extrapolating the findings to the larger population of patients with coronary artery disease. Nevertheless, the study presents two advantages. First, it is a prospective study with all risk factors and clinical findings determined before the occurrence of morbid events. Second, it is intentionally broad-based to include clinical findings, standard epidemiologic risk factors, psychosocial risk factors and, finally, angiographic findings in an effort to utilize the maximal amount of information relevant to predicting the patients' future.

Because our sample size was limited and the duration of our follow-up period was only 1 year, we grouped various untoward clinical events together under the heading of "morbid events." There were too few cases of specific morbid events (such as death) to warrant examining these events separately. By grouping these events together we were unable to examine whether various risk factors were associated with a particular outcome but, we were able to discern which factors were related to an assortment of "bad outcomes."

Medically versus surgically treated patients: We explored the relation between risk factors and morbidity, both with and without the surgically treated patients. Excluding surgically treated patients would introduce a bias in the study by excluding approximately 40 per cent of the follow-up sample. However, including these patients introduces another bias in that surgical treatment is likely to alter substantially the relation between incoming risk factors and developing morbidity. As Table III demonstrates, if risk factors are considered one can impressively predict future morbidity whether or not surgically treated patients are excluded. Thus the equation derived from the entire sample of 189 patients achieved a significance of $p < 0.00005$ and accurately predicted future morbidity 78 percent of the time, and that derived from the 110 medically treated men was significant at $p < 0.0001$ and predicted the fate of the cohort with 83 percent accuracy.

In both analyses the three most important variables were identical. These were: severity of angina, history of myocardial infarction and a family history of heart disease. Although their exact order of importance differed in the two analyses, fatigue and the absence of type A behavior were also key discriminatory variables.

Type A behavior as a risk factor: At first glance these findings seem to contradict the reports[14,15] relating type A behavior to both new and recurrent coronary events. In the setting of fatigue, chest pain and both a personal and a family history of heart disease, it may be that type B scores relate to exhaustion and emotional depletion, which have elsewhere been found to be harbingers of poor outcome in heart disease.[16]

Role of other risk factors: There were some differences in discriminating variables depending on the presence or absence of the surgically treated cohort. For the medically treated group alone, the presence of electrocardiographic Q waves, age, stress and low level

TABLE III

Summary Discriminant Analysis of Variables Related to Morbidity*

In medically treated patients (n = 10)	
Severity of angina	
History of myocardial infarction	
Family history of heart disease	
Electrocardiographic Q waves	
Age	
Stress	
Absence of type A behavior	
Low anger acknowledgment	
Fatigue	
Canonical correlation	0.52
Significance	$p < 0.0001$
Total predictive accuracy	83%
In total sample (n = 189)	
Severity of angina	
History of myocardial infarction	
Family history of heart disease	
Fatigue	
Absence of type A behavior	
Depression	
Low cholesterol	
Canonical correlation	0.42
Significance	$p < 0.00005$
Total predictive accuracy	78%

* All variables are listed in order of importance. Discriminating variables common to both analyses are printed in italics.

of acknowledgment of anger were discriminating variables. For the group as a whole, depression and low serum cholesterol were discriminating variables. The inverse relation between cholesterol level and morbidity may be a chance finding or may reflect the relative absence of beneficial HDL cholesterol.

The number of diseased vessels was not a discriminating variable, a surprising finding in view of much evidence to the contrary.[17–19] This finding is possibly explained by the strong association in our patients between surgical treatment and multiple vessel disease ($r = 0.37$, $p < 0.001$). If these patients had not undergone surgery, they might have accumulated more morbid events.

Finally, there was the impact of the shadow of the past; the family history of heart disease remained relevant to prognosis in this cohort of men already afflicted with heart disease. Something related to such a genetic or personal background persists in conveying substantial risk to the individual patient above and beyond the other risk factors.

Implications: Our approach has been to utilize the maximal amount of data derived from very different theories of risk. When scrutinized closely, many commonly used variables are so highly interrelated that they fail to aid in estimating patients' prognoses after other variables have been considered. By using a combination of clinical findings, laboratory findings, psychosocial assessment and data on epidemiologic exposure to risk factors, one can obtain sufficient information to estimate the prognosis of patients with coronary artery disease.

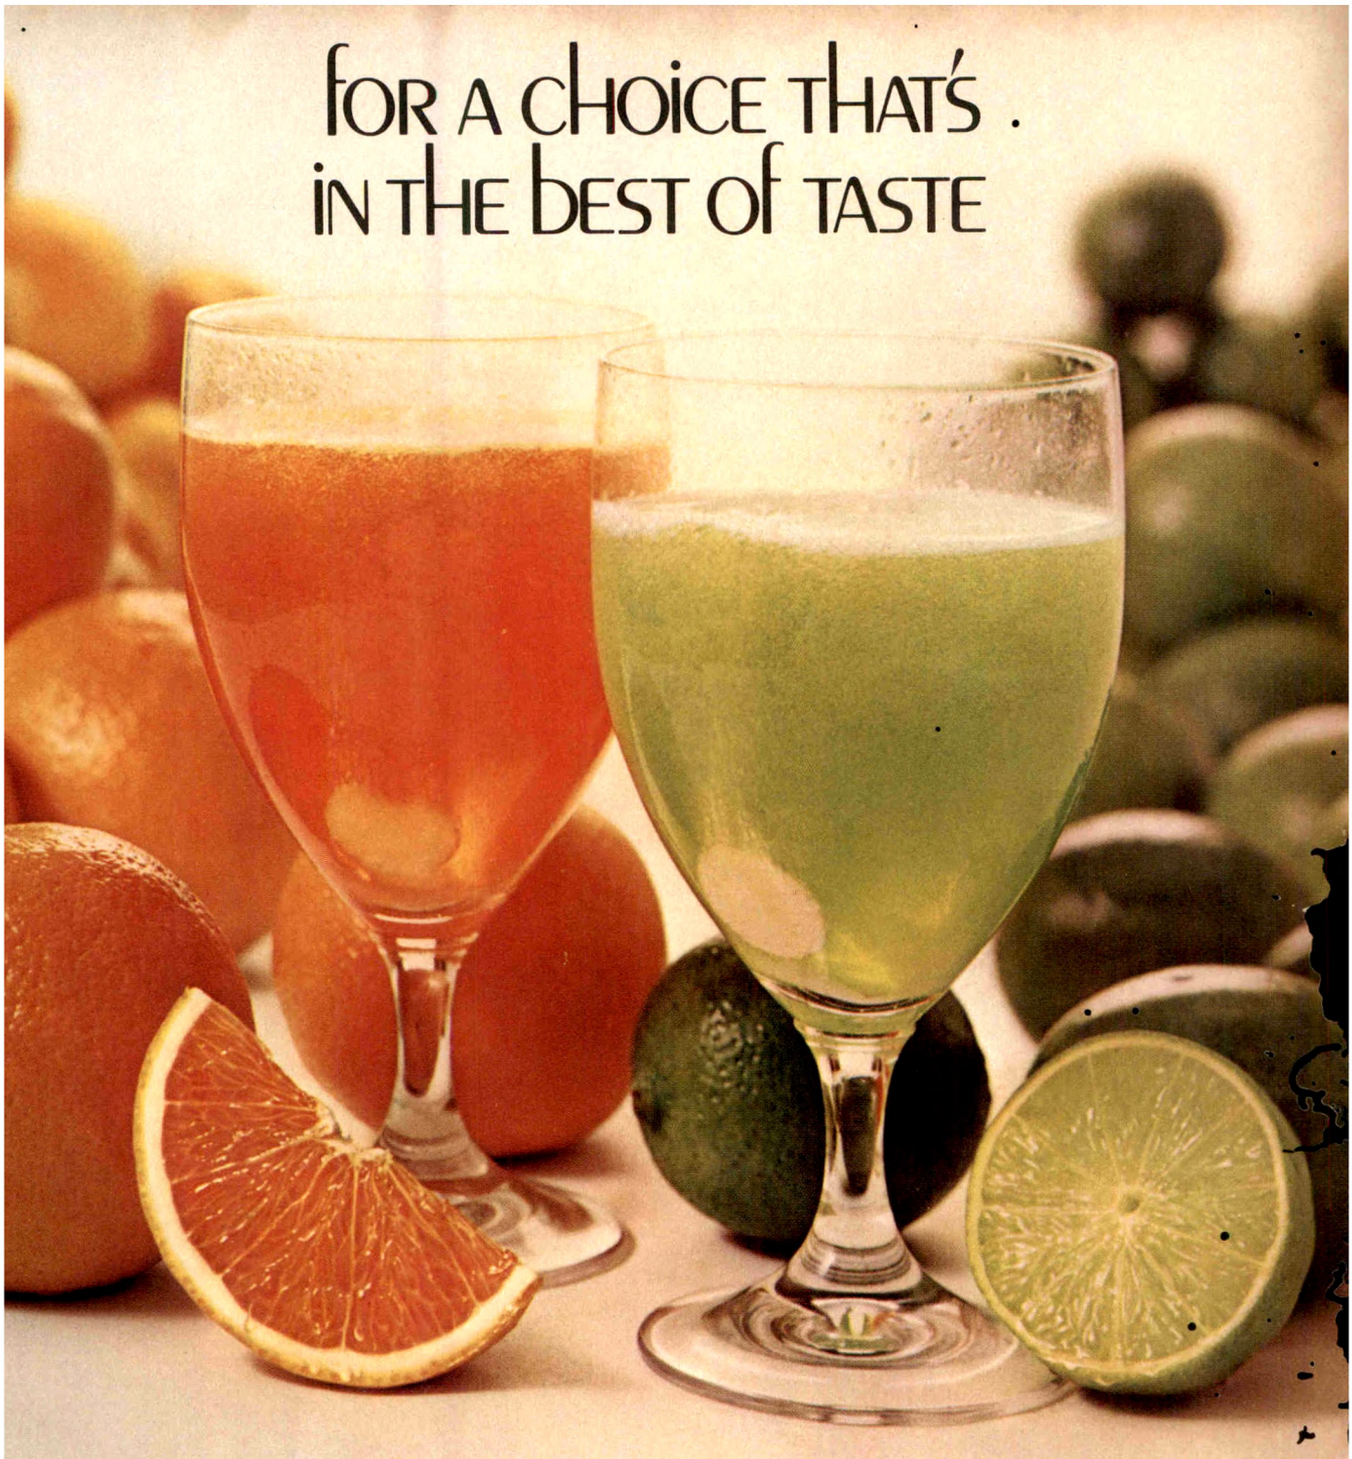
FOR A CHOICE THAT'S . IN THE BEST OF TASTE



K-LYTE®

Each effervescent tablet in solution supplies 25 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
The best of taste for over a decade

K-LYTE® DS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
Convenient once-a-day dosage

Prescribing Considerations

Indications: K-LYTE DS and K-LYTE are oral potassium supplements for therapy or prophylaxis of potassium deficiency. They are particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS and K-LYTE may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 K-LYTE DS tablet (50 mEq potassium) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily; 1 K-LYTE tablet (25 mEq potassium) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily. **NOTE: It is suggested that K-LYTE DS and K-LYTE be taken with meals and sipped slowly over a 5 to 10 minute period.**

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 and 100. K-LYTE effervescent tablets (orange or lime flavors) are available in cartons of 30 and 250. All tablets are individually foil wrapped.

Update on Oral Anticoagulation

TREATING MYOCARDIAL INFARCTION AND REDUCING THE THREAT OF THROMBOEMBOLISM

Each year in this country approximately one million people suffer acute myocardial infarctions. Rapid emergency treatment in coronary care units has been credited with reducing by up to one third the mortality among patients hospitalized with acute attacks.[1]

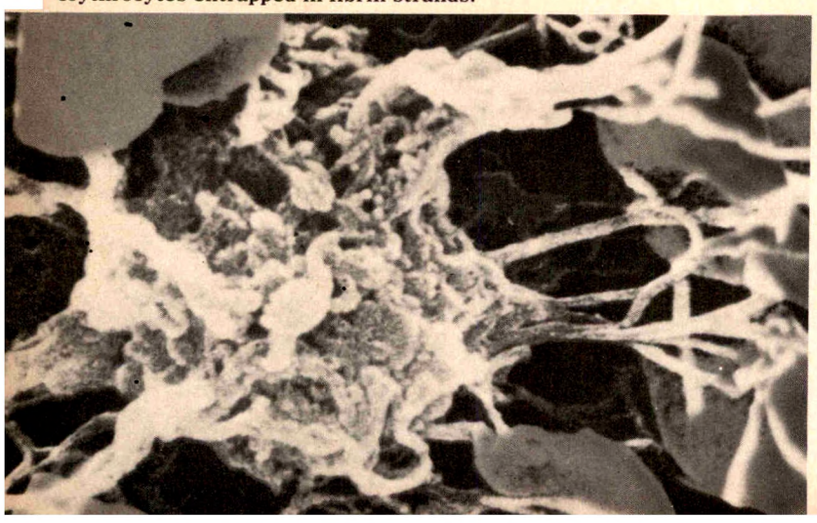
Thrombosis—incidence in myocardial infarction Following the damage to the heart itself, thromboembolism is perhaps the most serious sequel to myocardial infarction.

A study has demonstrated that there is a 39% incidence of calf vein thrombosis during the acute phase of myocardial infarction.[1]

Speed saves lives It has been reported that more than half the thrombi destined to occur in the calf veins form within 72 hours of myocardial infarction, and three-fourths form within the first week. Therefore, a number of investigators have recommended that antithrombotic measures should begin upon admission to the hospital and be effective almost immediately.[2]

Oral anticoagulants have a clinical value It has also been stated that the use of anticoagulants may reduce the frequency of calf vein thrombosis from 22 to 6.5%. The use of anticoagulants is subject to differing opinions regarding improved survival. A number of authorities recommend the use of anticoagulants in *all* patients who have no specific contraindications during the period of hospitalization.[1]

Scanning electron micrograph of 'Red' thrombus, formed by erythrocytes entrapped in fibrin strands.



One team of investigators in M.I. recommends providing full-dose warfarin while the patient is in the hospital and for several days afterward—

if the patient has had prior infarcts or thromboembolism
if the area of infarction is large
if complications (such as CHF or hypotension) require prolonged bed rest.

But, if post myocardial infarction syndrome (Dressler's syndrome) develops, anticoagulants should be discontinued, as pericardial hemorrhage or even cardiac tamponade may develop.[1]

Objectives and benefits of anticoagulation The use of anticoagulants in the acute phase of myocardial infarction has these potential advantages:[2]

prevention of deep vein thrombosis
reduction of embolization from cardiac mural thrombi
prophylaxis against extension of myocardial necrosis or long-term recurrence of infarction
reduction of overall mortality

If anticoagulants can inhibit the formation of deep vein thrombi, then the incidence of pulmonary embolism might be diminished—and pulmonary embolism has been estimated as a threat to life in 5,000 of the 500,000 myocardial infarction patients who are admitted to hospitals in this country each year.[2]

A look at survival One retrospective study of the use of anticoagulants in M.I. evaluated the survival of 1,307 patients from 20 hospitals in a large metropolitan community. The diagnosis of M.I. was based on predefined criteria, which included typical chest pain, serial ECG's, enzyme elevations, and autopsy findings.

Among anticoagulated patients, the adjusted in-hospital case-fatality rate was 18%. For patients who did not receive this treatment, the fatality rate was 31%. For survivors followed for as long as ten years, patients who had been anticoagulated still fared better than those not so treated.[3]

The authors of this study recognize

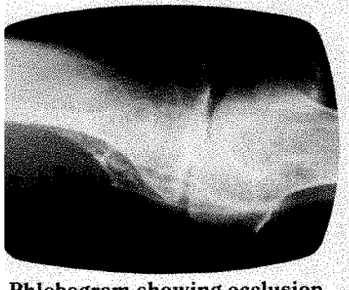
the drawbacks of using retrospective evidence and call for the formation of a multi-center, double-blind, randomized study on the use of anticoagulants in acute myocardial infarction.

Screening the high risk group The risk of DVT (deep vein thrombosis) is particularly great among certain patient groups:

patients with left ventricular failure
patients in shock
patients with arrhythmias
older patients
obese patients
patients with varicose veins
patients with previous myocardial infarction or thromboembolism

Screening techniques Diagnosis of DVT by physical examination may miss a significant number of clinically silent thrombi. There are, however, additional technological tools to help the clinician define more accurately the incidence of deep vein thrombosis. Among these are:

iodine-125 fibrinogen scanning—radioactively tagged fibrinogen is incorporated into actively forming thrombi and is detected on external sensors. This method is accurate for popliteal and calf vein thrombi, but not for iliofemoral thrombi.[2]



Phlebogram showing occlusion in deep vein of the upper calf.

venography—radiographic evidence of DVT is seen as a constant filling defect in venous projections, abrupt termination of a column of contrast material at a constant site, nonfilling of the deep veins, and presence of flow in collateral veins.[4]

ultrasound—Doppler ultrasound scanning can provide a fast, convenient, inexpensive reading of deep venous obstruction. This technique is potentially the most versatile and accurate method available. However, it demands considerable operator experience to insure maximal accuracy.[5]

impedance plethysmography—this technique results from the observation that blood volume changes in the calf produced by inflation or deflation of a thigh cuff produce variations in electrical resistance (impedance). Such changes are reduced in patients with thrombosis of the popliteal or more proximal veins.[4]

Patient compliance through education Providing the anticoagulated patient with information about his altered physical state and motivating him to comply with the therapeutic regimen constitute one of the most important aspects of health care.[6]

To determine the best way of imparting necessary information about anticoagulation to patients, a test was devised. One group of patients was given a brochure detailing the need for the medication and the importance of following the doctor's instructions. A second group of patients was given a programmed instruction booklet which was quite comprehensive in its teaching content, which included the action of warfarin, the purpose of prothrombin times, how to figure dosage from tablet strengths, possible complications and steps to take to control them.

When tested for learning and retention, the patients in the programmed instruction group scored significantly higher than the group given brochures only. In an area of medicine that relies so heavily on patient compliance, this report could be important in determining how medical information is communicated to the patient.[6]

The bottom line A postmortem study[7] underlines the importance of thrombosis in myocardial infarction. In this study of 173 patients with recurrent myocardial infarction, coronary occlusion due to thrombosis occurred in 54% of cases. Recent occlusive coronary thrombosis was 4 times less frequent in patients who received adequate anticoagulation (mean prothrombin level was 29 ± 5%).

And as one authority states:

"Rational use of anticoagulant therapy in the setting of acute myocardial infarction may save more than 8,000 lives a year in this country. Full advantage should be taken of this therapeutic opportunity."[2]

COUMADIN is an Endo registered U.S. trademark.

COUMADIN®

crystalline warfarin sodium, U.S.P.*

TABLETS

DESCRIPTION COUMADIN (crystalline warfarin sodium), a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of warfarin sodium virtually eliminates trace impurities present in amorphous warfarin sodium, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN (crystalline warfarin sodium) is therapeutically equivalent to amorphous warfarin sodium.

ACTIONS COUMADIN and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN (crystalline warfarin sodium) usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy—COUMADIN (crystalline warfarin sodium) is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1)central nervous system; (2)eye; (3)traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1)gastrointestinal, genitourinary or respiratory tracts; (2)cerebrovascular hemorrhage; (3)aneurysms—cerebral, dissecting aorta; pericarditis and pericardial effusions; (5)subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis, or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** major regional, lumbar block anesthesia and malignant hypertension.

WARNINGS Warfarin sodium is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN (crystalline warfarin sodium) are given together, a period of at least 5 hours should elapse after the last intravenous dose and 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when warfarin sodium is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Lactation—coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, severe allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN.

Concurrent use of anticoagulants with streptokinase or urokinase is not recommended and may be hazardous. (Please note recommendations accompanying these preparations.)

Abrupt cessation of anticoagulant therapy is not generally recommended, taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma, collagen disease; congestive heart failure, diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol, aminosalicylic acid; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cimetidine; cinchophen; clofibrate; COUMADIN (crystalline warfarin sodium) overdosage, dextran; dextrothyroxine, diazoxide, dietary deficiencies; diuretics†; disulfiram, drugs affecting blood elements, ethacrynic acid; glucagon; hepatotoxic drugs, indomethacin, inhalation anesthetics; mefenamic acid, methyldopa; methylphenidate; metronidazole; monoamine oxidase inhibitors; nalidixic acid; oxolinic acid; oxyphenbutazone; pyrazolones, phenylbutazone; phenyramidol, phenytoin, prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates; sulfinpyrazone; sulfonamides, long acting, sulindac, thyroid drugs, tolbutamide; triclofos sodium; trimethoprim/sulfamethoxazole; unreliable prothrombin time determinations.

*Present as crystalline sodium warfarin isopropanol clathrate.

†Increased and decreased prothrombin time responses have been reported.

COUMADIN is an Endo registered U.S. trademark.

EDO-924C Printed in U.S.A. Nov. 1980

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN (crystalline warfarin sodium) underdosage; diet high in vitamin K; diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (phenytoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN (crystalline warfarin sodium) include:

1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer, etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and a reaction consisting of hemorrhagic infarction and necrosis of the skin.

3. Priapism has been associated with anticoagulant administration, however, a causal relationship has not been established.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN (crystalline warfarin sodium) patient aids are available to physicians on request.

The administration and dosage of COUMADIN must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic anticoagulation are 1½ to 2½ times the normal prothrombin time (e.g. 18 to 30 seconds, with a control of 12 seconds).

Induction—40 to 60 mg for average acult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response. The basis for the no-loading dose regimen is that the depression of Factors II, IX, and X is not accelerated by the administration of a loading dose.

Maintenance—Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy—The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery—The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN (crystalline warfarin sodium) be adjusted to maintain the prothrombin time at approximately 1½ to 2½ times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN with Heparin—Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in emergency situations to administer sodium heparin initially along with COUMADIN. The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe.

It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, at least 5 hours after the last intravenous injection or 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN (crystalline warfarin sodium), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN (crystalline warfarin sodium, USP). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous warfarin sodium lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution.

50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg. pH is adjusted with sodium hydroxide, accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

Injection manufactured by Lypho-Med, Inc., Chicago, Illinois 60651 for Endo Laboratories, Inc.

INTRODUCING STATUS 1000

WITH AN IMAGINATION TO MATCH YOUR OWN

Status 1000, The ECG Monitor That Gives You Programmable Control Over Every Aspect Of The Stress Test.

Quinton's Status 1000 is the first ECG stress test system that lets you use your imagination to modify or reprogram at will the various elements of a stress test.

Not just treadmill protocol, but lead selection, ST sample point, recorder speed, patient name, final report content and length, blood pressure prompting, etc. Everything is in your control like it should be.

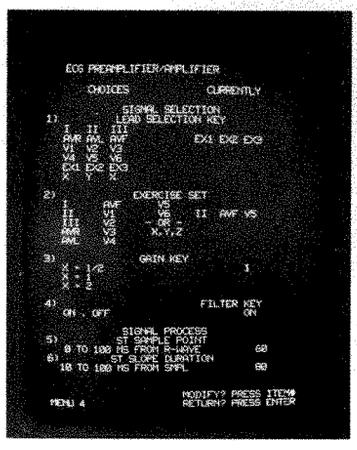
Use your professional imagination to create and program customized test procedures for pediatric, research, post-M.I., rehab., or out-patient situations.

Each physician in your institution can have their own preferred test procedure stored in memory.

With the Status 1000 you and your colleagues can customize test procedures based on the requirements of the patient, not the restrictions of the ECG system.

How The Sophisticated Status 1000 Makes Test Flexibility So Complete And Easy

With The Status 1000, Quinton introduces a new term, the "Stress Test Environment". It consists of 16 test elements. Each element, such as exercise lead set, or final report content, has parameters which you can establish or modify to suit your needs.



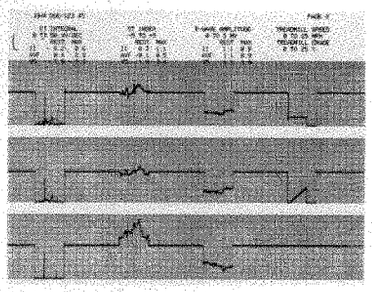
Yet, programming the Status 1000 is as easy as operating a pocket calculator, so special training is not required.

Comprehensive Data, Professionally Presented

In a single glance you see three channels of diagnostic quality ECG, averaged beats (both resting and current), heartrate, computed parameters, trend displays, stage number, stage time and elapsed time.

Plus, any abnormal beat will be instantly highlighted on the screen, then recorded and labeled automatically.

Your control extends to test reports, too. Printouts during the test may include averaged beats, rhythm strips, or full 12-leads. Final reports may include a wide variety of information. And each report is automatically labeled with pertinent data. Good bye work sheet.



Stay Ahead With The Status 1000

Because of the Status 1000's unparalleled flexibility and microprocessor technology its susceptibility to obsolescence is far less than other systems. And that makes it a good investment for you and your institution. Call Quinton toll free at 1-800-426-0538.

Dobuti
Dobutamine
For Short-Term
Inotropic Support in Patients w
Low-Output Cardiac Failure

Selectively Increases
Myocardial Contractility
with Consistent
Hemodynamic Improvements

Dobutrex®
Dobutamine HCl

For I.V. Injection
250 mg* in 20-ml-size vials
* Equivalent to dobutamine

Brief Summary
Consult the package literature for prescribing information.

Indications and Usage: Dobutrex® (dobutamine hydrochloride, Lilly) is indicated when parenteral therapy is necessary for inotropic support in the short-term treatment of adults with cardiac decompensation due to depressed contractility resulting either from organic heart disease or from cardiac surgical procedures.

In patients who have atrial fibrillation with rapid ventricular response, a digitalis preparation should be used prior to instituting therapy with Dobutrex.

Contraindication: Dobutrex is contraindicated in patients with idiopathic hypertrophic subaortic stenosis.

Warnings: 1. *Increase in Heart Rate or Blood Pressure*—Dobutrex may cause a marked increase in heart rate or blood pressure, especially systolic pressure. Approximately 10 percent of patients in clinical studies have had rate increases of 30 beats/minute or more, and about 7.5 percent have had a 50-mm Hg or greater increase in systolic pressure. Reduction of dosage usually reverses these effects promptly. Because dobutamine facilitates atrioventricular conduction, patients with atrial fibrillation are at risk of developing rapid ventricular response. Patients with preexisting hypertension appear to face an increased risk of developing an exaggerated pressor response.

2. *Ectopic Activity*—Dobutrex may precipitate or exacerbate ventricular ectopic activity, but it rarely has caused ventricular tachycardia.

Precautions: 1. **During the administration of Dobutrex, as with any adrenergic agent, ECG and blood pressure should be continuously monitored. In addition, pulmonary wedge pressure and cardiac output should be monitored whenever possible to aid in the safe and effective infusion of Dobutrex.**

2. Hypovolemia should be corrected with suitable volume expanders before treatment with Dobutrex is instituted.

3. Animal studies indicate that Dobutrex may be ineffective if the patient has recently received a beta-blocking drug. In such a case, the peripheral vascular resistance may increase.

4. No improvement may be observed in the presence of marked mechanical obstruction, such as severe valvular aortic stenosis.

Usage Following Acute Myocardial Infarction—Clinical experience with Dobutrex following myocardial infarction has been insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex® (dobutamine hydrochloride, Lilly) for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex® (dobutamine hydrochloride, Lilly) is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add an additional 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstituted time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250,500, and 1000 mcg/ml

Drug Delivery Rate (mcg/kg/min)	Infusion Delivery Rate 250 mcg/ml* (ml/kg/min)	500 mcg/ml† (ml/kg/min)	1000 mcg/ml‡ (ml/kg/min)
2.5	0.01	0.005	0.0025
5	0.02	0.01	0.005
7.5	0.03	0.015	0.0075
10	0.04	0.02	0.01
12.5	0.05	0.025	0.0125
15	0.06	0.03	0.015

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

Sophisticated pa

Only after you have reached the ultimate in sophistication can you truly simplify. The 6-3-1-0 family of Programalith® Interrogatable™ pacemakers from Pacesetter Systems, Inc. is evidence of that simple truth.

The simplest of these interrogatable pacemakers, the Programalith 'O', is perhaps the most sophisticated of all, in its way.

The Programalith 'O' requires no programming, yet it can be interrogated for all measured data (see chart at right), providing invaluable assistance in long-term patient management.

The Programalith 'O' can tell quite a story: It provides information for calculating the remaining battery capacity of the implanted pacemaker, gives the physician data for assessing possible lead problems – *and* their location – and provides battery impedance and battery current as well.

The story of 'O' – Pacesetter Systems style – may be one of the most important stories of the year, for physicians, for patients, and for the pacer industry itself.

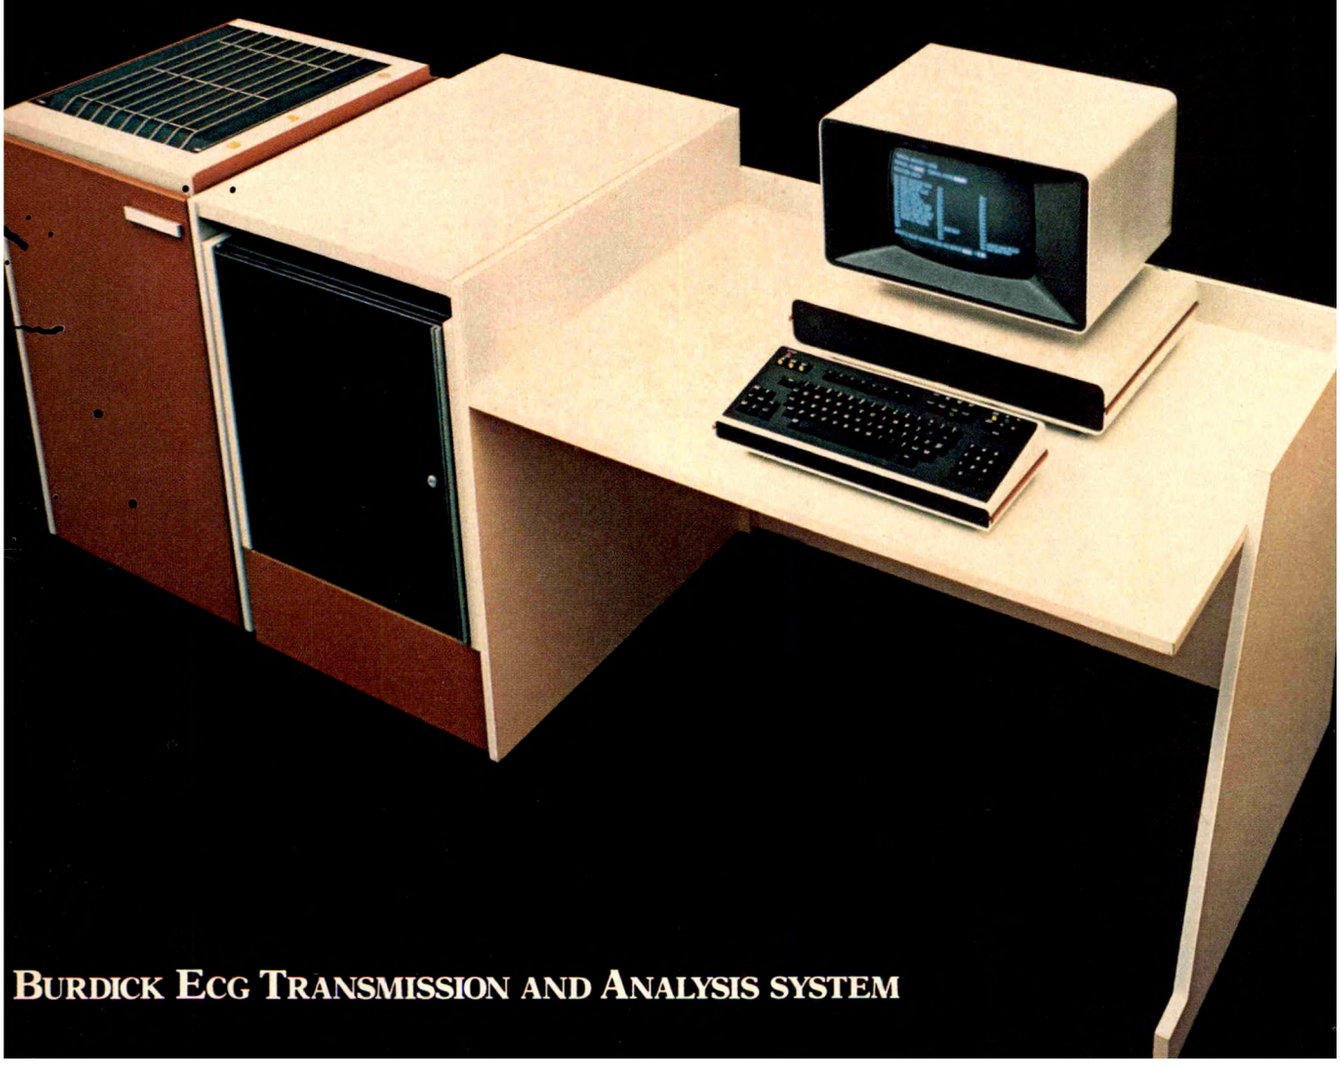
BURDICK INTRODUCES

BETA



BURDICK ECG TRANSMISSION AND ANALYSIS SYSTEM

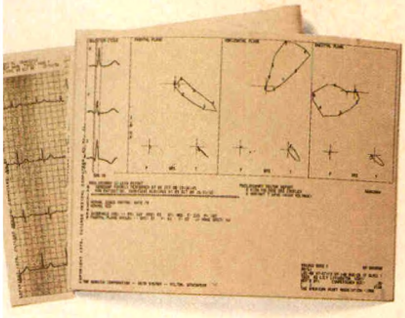
IT'S FIVE FULL STEPS AHEAD OF ANY OTHER COMPUTERIZED ECG SYSTEM.

Computerized ECG technology has just made a remarkable advance. Burdick has taken its leadership experience in the field of electrocardiography and combined it with some of the most sophisticated medical computer technology available today.

The result is the Burdick BETA™, a computerized ECG system that combines today's most comprehensive ECG analysis with a complete backup for acquisition, storage and retrieval that is both efficient and cost-effective. In fact, BETA is ahead of any other computerized ECG system in five important ways.

1. THE ONLY SYSTEM WITH SCALAR/VECTOR ANALYSIS

The combination of 12-lead Scalar (ECG) data and 3-dimensional Vector (VCG) data in a single, complete analysis is the Burdick breakthrough that assures a more complete, accurate diagnosis. BETA is the



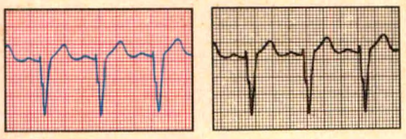
only computerized ECG system that combines simultaneous Scalar/Vector data with the technology of automated computer analysis, providing patient diagnosis of enhanced sensitivity and specificity.

2. THE ONLY SYSTEM THAT STORES AND RETRIEVES OPTICALLY AND NUMERICALLY CORRECT ECGS

Until now, computerized ECG systems have sacrificed the quality of their retrieved ECGs to achieve greater data storage.

BETA is the first system to offer cost-effective, unlimited, on-line mass storage of ECG/VCGs, with fast retrieval by means of a unique master indexing system using patient or hospital coding.

While some systems indiscriminately compress at ratios of as much as 15 to 1, BETA virtually eliminates data compression. The result is that users are able to retrieve cardiograms that are optically and numerically correct, with no degradation of original data. That, of course, makes possible accurate re-analysis.



Original ECG

BETA'S non-compressed data

3. THE ONLY SYSTEM IN WHICH ALL SATELLITES HAVE TOTAL ACCESS TO HOST HOSPITAL CAPABILITIES

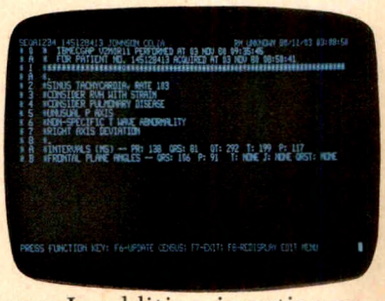
In a BETA installation, satellite hospitals are more than just appendages. They share fully in all the capabilities enjoyed by the host hospital, such as security, mass storage, Scalar/Vector analysis, free-form editing, and other options, including direct communication with each satellite hospital medical information system.

That way the satellites have all the advantages of their own BETA system without the capital expense. Conversely, host hospitals can offer comprehensive, yet cost-effective service to prospective satellite hospitals.

4. THE ONLY STORAGE SYSTEM DESIGNED FOR FREE-FORM EDITING

All editing of computer-generated analysis on the BETA video display terminal is done in plain language. The physician and staff can enter their changes or additions in the words they choose, any place in the text.

It is not necessary to memorize codes, reducing possibility of



error. In addition, insertion or deletion of words or sentences can be made anywhere in the text. This eliminates footnote form editing.

5. THE ONLY FULL-RANGE SYSTEM WITH COMPLETE MODULARITY FOR FUTURE NEEDS

You can start with an economical base system. And as your needs develop, you can add Vector analysis, additional storage capacity and other functions. There is no need to replace original equipment to get increased system capability.

And since BETA stores completely re-analyzable cardiograms, your on-line data base always remains intact as you build the system.

PLUS . . . MULTI-LEVEL PATIENT DATA SECURITY

With the Burdick BETA System you have available several levels of patient data security that virtually eliminate the possibility of unauthorized access and/or alterations to stored data. The system assures the hospital of complete integrity and privacy of patient information

For the complete story on Burdick's remarkable BETA System, call toll-free 800-356-0701. In Wisconsin call 608-868-7631:

[1] Data on file, Boehringer Ingelheim Ltd.

Please see brief summary on last page for warnings, precautions, and adverse reactions.

Combipres is not indicated for initial therapy. It is for patients responsive to its components given separately in equivalent dosages.

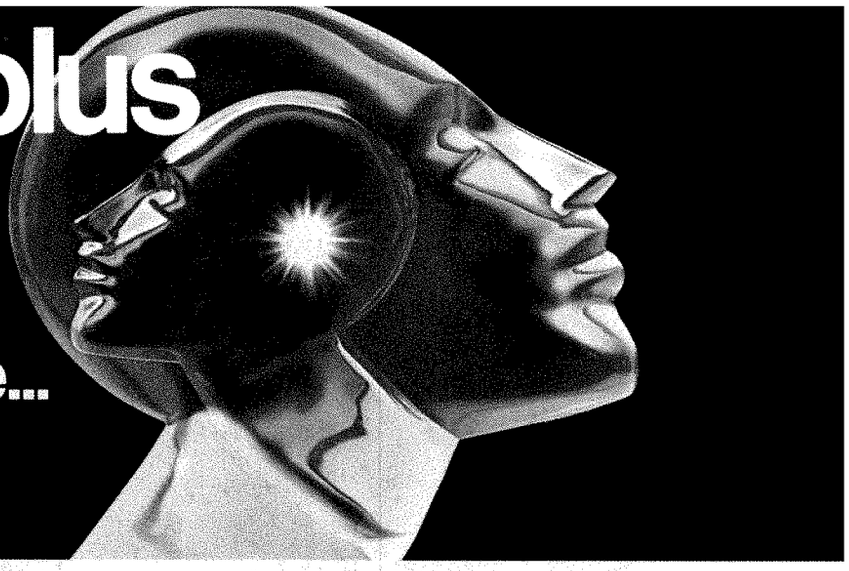
Combipres®

Each tablet contains: Catapres® (clonidine HCl) 0.1 or 0.2 mg, and chlorthalidone, 15 mg

.1 and .2

Hypertension

Alpha...plus



hold the pressure...
hold the patient...

Combipres® .1 and .2

Each tablet contains: Catapres® (clonidine HCl) 0.1 or 0.2 mg, and chlorthalidone, 15 mg

Warning: This fixed combination drug is not indicated for initial therapy of hypertension. Hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension is not static, but must be reevaluated as conditions in each patient warrant.

Indication: The drug is indicated in the treatment of hypertension (see box warning).

Contraindications: Patients with known hypersensitivity to chlorthalidone and patients with severe renal or hepatic diseases.

Warnings: Tolerance may develop in some instances necessitating a reevaluation of therapy.

Usage in Pregnancy: In view of embryotoxicity findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefit outweighs the potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of Combipres in children.

Precautions: When discontinuing Combipres, reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of Combipres therapy or by intravenous phentolamine.

Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect of the clonidine hydrochloride component. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other antihypertensive agent, Combipres should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Combipres should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmological findings have been recorded with Catapres, in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 months or longer.

Patients predisposed toward or affected by diabetes should be tested periodically while receiving Combipres, because of the hyperglycemic effect of chlorthalidone.

Because of the possibility of progression of renal failure, periodic determination of the BUN is indicated. If, in the physician's opinion, a rising BUN is significant, the drug should be stopped.

The chlorthalidone component of Combipres may lead to sodium and/or potassium depletion. Muscular weakness, muscle cramps, anorexia, nausea, vomiting, constipation, lethargy or mental confusion may occur. Severe dietary salt restriction is not recommended in patients receiving Combipres.

Periodic determinations of the serum potassium level will aid the physician in the detection of hypokalemia. Extra care should be given to detection of hypokalemia in patients receiving adrenal corticosteroids, ACTH or digitalis. Hypochloremic alkalosis often precedes other evidence of severe potassium deficiency. Frequently, therefore, more sensitive indicators than the potassium serum level are the serum bicarbonate and chloride concentrations. Also indicative of potassium depletion can be electrocardiographic alterations such as changes in conduction time, reduction in amplitude of the T wave; ST segment depression; prominent U wave. These abnormalities may appear with potassium depletion before the serum level of potassium decreases. To lessen the possibility of potassium deficiency, the diet, in addition to meat and vegetables, should include potassium-rich foods such as citrus fruits and bananas. If significant potassium depletion should occur during therapy, oral potassium supplements in the form of potassium chloride (3 to 4.5 gm/day), fruit juice and bananas should be given.

Adverse Reactions: The most common reactions are dry mouth, drowsiness and sedation. Constipation, dizziness, headache, and fatigue have been reported. Generally these effects tend to diminish with continued therapy.

Clonidine hydrochloride: Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalities in liver function tests; one case of possible drug-induced hepatitis without icterus and hyperbilirubinemia in a patient receiving clonidine hydrochloride, chlorthalidone and papaverine hydrochloride. Weight gain, transient elevation of blood glucose, or serum creatine phosphokinase; congestive heart failure, Raynaud's phenomenon; vivid dreams or nightmares, insomnia, other behavioral changes, nervousness, restlessness, anxiety and mental depression. Also rash, angioneurotic edema, hives, urticaria, thinning of the hair, pruritus not associated with a rash; impotence, urinary retention; increased sensitivity to alcohol, dryness, itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecomastia, weakly positive Coombs' test, asymptomatic electrocardiographic abnormalities manifested as Wenckebach period or ventricular trigeminy.

Chlorthalidone: Symptoms such as nausea, gastric irritation, anorexia, constipation and cramping, weakness, dizziness, transient myopia and restlessness are occasionally observed. Headache and impotence or dysuria may occur rarely. Orthostatic hypotension has been reported and may be potentiated when chlorthalidone is combined with alcohol, barbiturates or narcotics. Skin rashes, urticaria and purpura have been reported in a few instances.

A decreased glucose tolerance evidenced by hyperglycemia and glycosuria may develop inconsistently. This condition, usually reversible on discontinuation of therapy, responds to control with antidiabetic treatment. Diabetics and those predisposed should be checked regularly.

As with other diuretic agents hypokalemia may occur (see Precautions). Hyperuricemia may be observed on occasion and acute attacks of gout have been precipitated. In cases where prolonged and significant elevation of blood uric acid concentration is considered potentially deleterious, concomitant use of a uricosuric agent is effective in reversing hyperuricemia without loss of diuretic and/or antihypertensive activity.

Idiosyncratic drug reactions such as aplastic anemia, thrombocytopenia, leukopenia, agranulocytosis, and necrotizing angiitis have occurred, but are rare.

The remote possibility of pancreatitis should be considered when epigastric pain or unexplained gastrointestinal symptoms develop after prolonged administration.

Other adverse reactions which have been reported with this general class of compounds include: jaundice, xanthopsia, paresthesia and photosensitization.

Overdosage: *Catapres (clonidine hydrochloride):* Profound hypotension, weakness, somnolence, diminished or absent reflexes and vomiting followed the accidental ingestion of Catapres by several children from 19 months to 5 years of age. Gastric lavage and administration of an analeptic and vasopressor led to complete recovery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-minute intervals abolishes all effects of Catapres overdosage.

Chlorthalidone: Symptoms of overdosage include nausea, weakness, dizziness, and disturbances of electrolyte balance. There is no specific antidote, but gastric lavage is recommended, followed by supportive treatment. Where necessary, this may include intravenous dextrose and saline with potassium administered with caution.

How Supplied: Combipres® 0.1 (Each tablet contains clonidine hydrochloride 0.1 mg + chlorthalidone 15 mg). It is available as pink, oval, single-scored compressed tablets in bottles of 100.

Combipres® 0.2 (Each tablet contains clonidine hydrochloride 0.2 mg + chlorthalidone 15 mg). It is available as blue, oval, single-scored compressed tablets in bottles of 100.

For complete details, please see full prescribing information.

Lung Biopsy With Frozen Section as a Diagnostic Aid in Patients With Congenital Heart Defects

MARLENE RABINOVITCH, MD
ALDO R. CASTANEDA, MD, FACC
LYNNE REID, MD

Boston, Massachusetts

In eight patients with congenital heart defects and equivocal preoperative hemodynamic data, lung biopsy with frozen section was performed and quantitative morphometric analysis carried out to help select a palliative or corrective surgical procedure. During catheterization it had been possible in only six of the eight patients to enter the pulmonary artery and obtain pressure measurements; four patients had moderate to severe elevation of pulmonary vascular resistance whereas the other two had only mild elevation of pulmonary arterial pressure, but they were being considered for a Fontan procedure.

The lung biopsy tissue was taken inflated and fixed inflated in hot glutaraldehyde. From cryostat sections arterial concentration was assessed relative to alveolar concentration, and the degree of arterial muscularity was assessed by wall thickness and extension of muscle; the more advanced Heath-Edwards arterial changes were also evaluated. On the basis of the morphologic assessment, six of the eight patients underwent corrective surgery and two underwent a palliative procedure. Postoperative hemodynamic data available in four of the patients who underwent corrective surgery revealed either a significant reduction in pulmonary vascular resistance or return to a normal level of pulmonary arterial pressure, whereas no change has occurred in the one patient studied who underwent a palliative procedure. Assessment of pulmonary arterial development and structure on lung biopsy with frozen section proved helpful in deciding between a palliative and corrective surgical procedure.

Patients with congenital heart defects complicated by pulmonary vascular changes and elevated pulmonary vascular resistance may not be suitable candidates for corrective surgery.[1–5] Whereas severe and irreversible elevation in pulmonary vascular resistance precludes a favorable hemodynamic result after surgical closure of a ventricular septal defect,[1,2] even mild elevation will result in right heart failure after a Fontan-type procedure for tricuspid atresia and related lesions.[5]

The level of pulmonary vascular resistance determined at preoperative cardiac catheterization reflects the behavior of the pulmonary circulation at one time only and may not be representative. In patients with either severe subpulmonary stenosis or atresia and a surgically created systemic to pulmonary arterial shunt, it may be very difficult to enter the pulmonary artery and to obtain pressure measurements; in these cases, the catheter itself may compromise pulmonary blood flow and pulmonary arterial pressure may be falsely decreased. In some patients, because of the size or the configuration of the systemic to pulmonary arterial anastomosis, it may not be possible or prudent to enter the pulmonary artery at all. Moreover, direct assessment of pulmonary arterial pressure through pulmonary venous wedge pressure measurement has not proved reliable.[6]

It is therefore important to have an alternative way to assess pulmonary circulation. Through morphometric analysis of lung biopsy tissue, we have determined the type and severity of abnormalities of structure

and growth of the peripheral pulmonary arteries that reflect increased pulmonary blood flow, pressure or resistance.[7] We have now applied these quantitative techniques of analysis to examine lung biopsy tissue prepared by frozen section at the time of operation. In patients whose hemodynamic data were equivocal, unreliable or could not be obtained, this technique has been useful in deciding whether to perform a palliative or a corrective operation.

Methods

Study Patients (Table I)

In eight patients with congenital heart defects, whose ages ranged from 1 to 24 years, it was not certain from the hemodynamic and angiographic data whether a corrective or palliative surgical procedure was indicated. Two patients (Cases 1 and 2) had d-transposition of the great arteries with associated ventricular septal defect; two (Cases 3 and 4), complete common atrioventricular canal; three (Cases 5 to 7), tricuspid atresia (all with severe subpulmonary stenosis and one or more previously surgically created systemic to pulmonary arterial shunts); and one (Case 8), tetralogy of Fallot with pulmonary atresia and large aortopulmonary collateral vessels.

Cardiac catheterization findings: In six of the eight patients, the pulmonary artery was entered and pressure measured; in the other two this was not technically possible. In three of the six patients whose pulmonary arterial pressure was measured, pulmonary vascular resistance was elevated (8 to 14 U/m^2). In one of these patients (Case 3), the pulmonary vascular bed responded to priscoline (1 mg/kg given intravenously) with a decrease in pulmonary vascular resistance of 6 U/m^2, but in another patient (Case 2), neither priscoline nor breathing 100 percent oxygen for 15 minutes caused any change. The third patient with elevated pulmonary vascular resistance (Case 4) was extremely restless during cardiac catheterization and was not at steady state long enough to be tested satisfactorily with oxygen or priscoline. In a fourth patient (Case 1), pulmonary vascular resistance was only mildly elevated, but this patient had d-transposition of the great arteries complicated by both a ventricular septal defect and a patent ductus arteriosus and was considered at high risk for the development of pulmonary vascular disease.[8,9] Because it is particularly difficult to calculate reliably the level of pulmonary vascular resistance in d-transposition of the great arteries, it was believed this might be a misleading result.[10,11]

Two other patients had only mildly elevated pulmonary arterial pressure, but both were being considered for a Fontan procedure.[5] Because the Fontan procedure involves either a conduit or a direct anastomosis between the right atrium and the pulmonary artery, it must be ensured that the level of pulmonary arterial pressure and resistance be normal postoperatively. In one of these patients (Case 6), the level of pulmonary arterial pressure had been normal at cardiac

A-V = atrioventricular; dTGA = d-transposition of the great arteries; NE = not entered; PA = pulmonary artery; PDA = patent ductus arteriosus; Postop = postoperative; P_{pa} = mean pulmonary arterial pressure; Preop = preoperative; Rp = pulmonary vascular resistance; Rs = systemic vascular resistance; Rp/Rs = ratio of pulmonary to systemic vascular resistance. RV = right ventricle; S/P = status postoperative; VSD = ventricular septal defect.

catheterization 2 years before operation, but intraoperatively the pulmonary arterial pressure was elevated. It was uncertain whether this elevation was the effect of anesthesia or truly reflected the state of the pulmonary vascular bed. In the other patient (Case 5), pulmonary arterial pressure varied with the position of the catheter; when the measurement was taken close to the orifice of the systemic to pulmonary arterial shunt the value was high, whereas when it was recorded more distally, it was normal.

The pulmonary artery could not be entered and pressure could not be recorded in two patients. One of these patients had tricuspid atresia and was being considered for a Fontan procedure; two different systemic to pulmonary arterial shunts had previously been produced surgically, but it was not possible to enter either shunt. The other patient had tetralogy of Fallot with pulmonary atresia and large tortuous aorto-pulmonary collateral vessels; because no obvious stenoses were identified angiographically, severe pulmonary vascular changes in the lung were suspected.[12]

Method of Lung Biopsy

The lung biopsy was performed after the chest was opened; in all patients tissue was taken from the medial aspect of the right upper lobe, but in one patient tissue was also taken from the left upper lobe. First, the lungs were fully inflated at a pressure ranging between 16 and 32 cm of water depending on the weight of the patient. Two "C" clamps were placed on the lung and a piece of tissue 1 by 2 by 0.5 cm was isolated (Fig. 1). The tissue between the clamps was incised and the distal clamp containing the inflated tissue was submerged for 10 minutes in warmed (40° C) 2.5 percent glutaraldehyde solution. The glutaraldehyde was made up in 0.2 molar cacodylate buffer; the final pH was 7.4 and osmolarity 434 mosmol/liter. The clamp was then released and a piece of tissue 1 by 0.2 by 0.5 cm was cut perpendicular to the pleural surface and mounted for cryostat sections. Six sections, taken at least five sections apart, were flame-fixed to albuminized slides to which elastic Van Gieson stain was applied. This stain is most useful for measuring the thickness of the arterial muscular coat and for assessing the degree of extension of muscle into small peripheral arteries. The remaining tissue was kept submerged in glutaraldehyde for an additional 2 hours of fixation, after which routine paraffin embedding was carried out. Twenty-four hours later, tissue sections, stained with elastic van Gieson in addition to hematoxylin-eosin and Gomori's trichrome stain, were available for comparison with the frozen sections.

Analysis of Lung Biopsy Tissue

Frozen section morphometric analysis: Morphometric analysis of all the arteries of all the fields was carried out in each of the six frozen sections. Although the same larger arteries could be identified in all sections, a few additional smaller arteries were generally found in each consecutive section. It was usually possible to identify 10 to 15 arteries in 5 to 10 fields (power × 20) in each section.

The following features of peripheral arterial structure were studied: The external diameter of an artery was measured with a calibrated eyepiece micrometer between the external elastic laminas across the shorter axis of the vessel. Wall thickness was measured across the shorter axis from external to internal elastic lamina because this has been shown to represent the true wall thickness even in vessels cut obliquely.[13] Percent wall thickness was then calculated:

$$\frac{2 \times \text{Wall thickness}}{\text{External diameter}} \times 100 = \% \text{ Wall thickness}$$

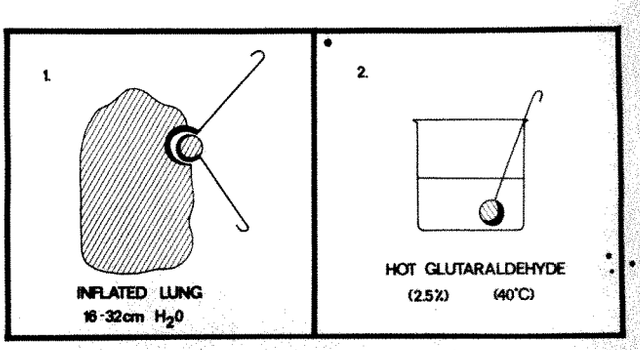

FIGURE 1. Diagrammatic representation of (1) an inflated lung with 2 C clamps on the upper medial aspect, and (2) the C clamp containing the biopsy tissue submerged in hot glutaraldehyde.

Arteries were grouped according to size and the percent wall thickness calculated for each size range. Where a small artery accompanied a small airway, it was characterized or landmarked by reference to the type of airway it accompanied: The levels recognized were preacinar, terminal bronchiolus, respiratory bronchiolus, alveolar duct and alveolar wall. In this manner, the structure of the artery related to airway level offers one way of assessing extension of muscle along the arterial pathway. Thus, increased arterial muscularity is apparent from an increased wall thickness related to the size of an artery or to the presence of muscle in arteries that are either smaller or in a more peripheral position along the arterial pathway than is normal. The number of arteries larger than 10 μm and alveoli were counted in each section and expressed as a ratio. This made allowance for any difference in the degree of inflation in the various biopsy tissues. The value obtained for each morphometric feature was compared with the previously established age-related normal value[7,13,14] (Table II).

The biopsy tissue was then graded A, B or C according to the severity of the morphologic changes by a system previously described[7] (Fig. 2). In this system, each new grade requires that all the features of the previous grade be present as well. On the basis of the results of our previous study,[7] we are able, from the grade given to a lung biopsy specimen, to predict whether the level of pulmonary arterial pressure is in the normal range or elevated, or whether the pulmonary vascular resistance is elevated and, in part, the degree of that elevation (Fig. 2).

TABLE II

Normal Morphometric Values on Lung Biopsy

Age	Alveolar Wall Muscular Arteries* (%)	Percent Wall Thickness of Muscular Arteries >50 μ External Diameter†* (%)	Arteries per 100 Alveoli‡
Newborn	0	20	5
4 mo	0	10	5
2 yr	0	10	8
6 yr	31	10	10
Adult	50	10	10

* Upper limit of normal range. † 2 × wall thickness/external diameter × 100. ‡ Lower limits of normal range.

	MORPHOLOGY	PHYSIOLOGY
A.	ABNORMAL EXTENSION OF MUSCLE	↑ PULMONARY BLOOD FLOW
B.	INCREASED WALL THICKNESS if > 1.5 x nl, often if > 2 x nl, always	↑ PULMONARY ARTERY PRESSURE
C.	REDUCED ARTERY NUMBER (usually associated with reduced artery size)	↑ PULMONARY VASCULAR RESISTANCE (≥ 3.5 u/M^2)

FIGURE 2. Morphometric grades of pulmonary vascular disease as they relate to physiology. When the increased wall thickness is greater than twice normal (nl), the designation "late" grade B is given. ↑ = increased.

The biopsy tissue was also analyzed for the more severe structural changes described by Heath and Edwards[15] *and graded accordingly.* Changes of late grade III and grade IV, occlusion and dilatation, respectively, have been shown to be associated with severe and irreversible elevation in the level of pulmonary vascular resistance.[16] The report of the lung biopsy analysis was conveyed to the operating surgeon within 30 minutes from the time the tissue was first obtained.

Analysis of paraffin-embedded sections: It was possible to analyze the paraffin-embedded sections available 24 hours later, in more detail than the frozen sections. Because the former were better fixed and easier to cut, there was less distortion of the tissue. In some cases, this analysis allowed for as much as a two-fold increase in the number of arteries satisfactory for counting and measuring. Also, because the alveolar architecture was better preserved, assessing the concentration of arteries relative to alveoli could be done with greater confidence. The degree of extension of muscle into peripheral arteries was evaluated as described for the frozen section. Because more arteries were measured and, because time was not a factor it was also possible after analysis of the paraffin-embedded sections to calculate a mean and standard error of percent wall thickness for arteries at different airway levels (that is, respiratory bronchiolus, terminal bronchiolus) and for arteries in different diameter ranges (that is, 50, 50 to 99, 100 to 149 and 150 to 199 μ).

Statistical analysis: Findings in the frozen and standard microscopic sections, with respect to the degree of peripheral extension of muscle, the medial wall thickness of the normally muscular arteries and arterial concentration, were compared with the paired *t* tests; a probability (p) value greater than 0.05 was judged to indicate a significant difference

Postoperative Hemodynamic Assessment

In five of the eight patients, postoperative hemodynamic measurements of pulmonary arterial pressure and resistance were also available. In three, complete cardiac catheterization with measurement of oxygen consumption was carried out 6 months to 1 year after operation; the other two patients underwent intracardiac monitoring of pulmonary arterial pressure in the immediate postoperative period and pulmonary vascular resistance was calculated using pulmonary blood flow assessed with the thermodilution technique.

Results

Comparison of frozen and final section (Table I): Analysis of the pulmonary vascular changes revealed similar findings on both the frozen section of the lung biopsy specimen and the paraffin-embedded section (Fig. 3 to 6). This was true especially for the degree of abnormal extension of muscle into small peripheral arteries and for the percent wall thickness of the normally muscular arteries. The concentration of small peripheral arteries was judged to be either the same or somewhat increased in the frozen than in the final paraffin-embedded section. However, the difference was not great and only altered the morphometric grade in one patient (Case 3). Also, knowledge of the value obtained from the final section would not have changed the intraoperative decision to perform corrective surgery. Assessment of the more advanced structural changes of Heath and Edwards revealed similar findings in the frozen and paraffin-embedded sections.

Lung biopsy analysis and prognosis: Patient 2 with d-transposition of the great arteries, a ventricular septal

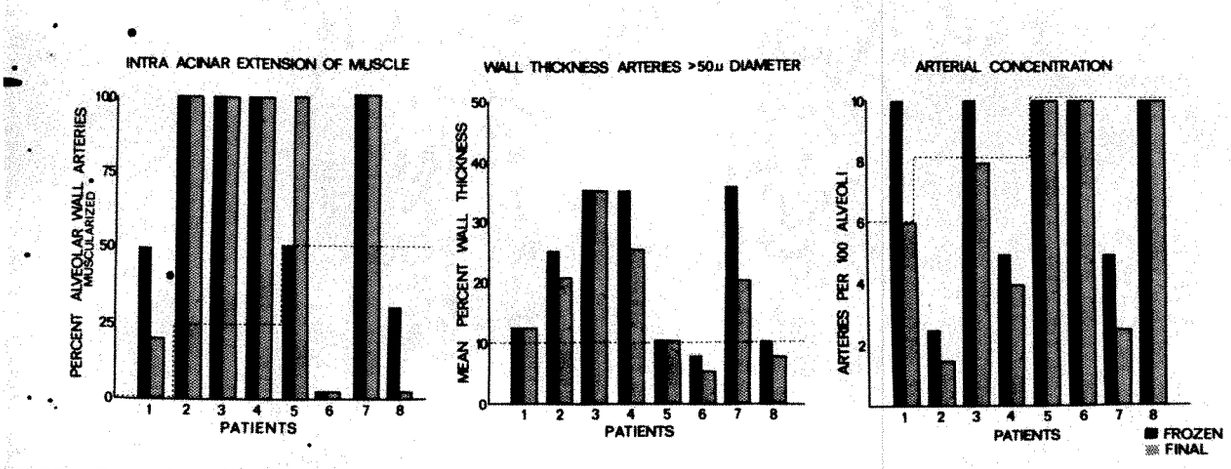

FIGURE 3. Comparison of the quantitative morphometric evaluation by frozen section (**solid bars**) and by paraffin-embedded section (**dotted bars**) of intraacinar extension of muscle, percent wall thickness of normally muscular arteries and arterial concentration expressed as arteries per 100 alveoli. The **top of each bar** represents the upper limit if a range of values was obtained, for example, for percent wall thickness. The **horizontal dotted line** represents the upper limit of normal range for each feature related to the age of the patient it crosses.

defect and fixed elevation in pulmonary vascular resistance had severe structural changes in the lung biopsy tissue—that is, morphometric grade C, including a severe reduction in arterial concentration as well as Heath-Edwards late grade III changes. After a palliative Mustard procedure was performed,[17] this patient had dramatic improvement in her symptoms; but on follow-up cardiac catheterization 6 months later, the pulmonary vascular resistance was still very high and did not respond to breathing of 100 percent oxygen. Two other patients (Cases 3 and 4), both with common atrioventricular canal and elevated pulmonary vascular resistance, also had grade C morphometric changes but a less severe reduction in the number of arteries than that observed in Patient 2, and none of the severe structural changes of Heath-Edwards. Both underwent complete correction of their defect and had an uncomplicated postoperative course. Only one of these patients (Case 3) has been restudied hemodynamically and in the immediate postoperative period. The pulmonary arterial pressure had decreased to half systemic levels and the pulmonary vascular resistance was significantly decreased. The patient (Case 1) with d-transposition of the great arteries, pulmonary arterial pressure at systemic levels and only mild elevation in pulmonary vascular resistance had grade B changes on lung biopsy. Complete repair was carried out and he had an uneventful postoperative course. Six months later cardiac catheterization was repeated because pulmonary venous obstruction was suspected. His pulmonary arterial

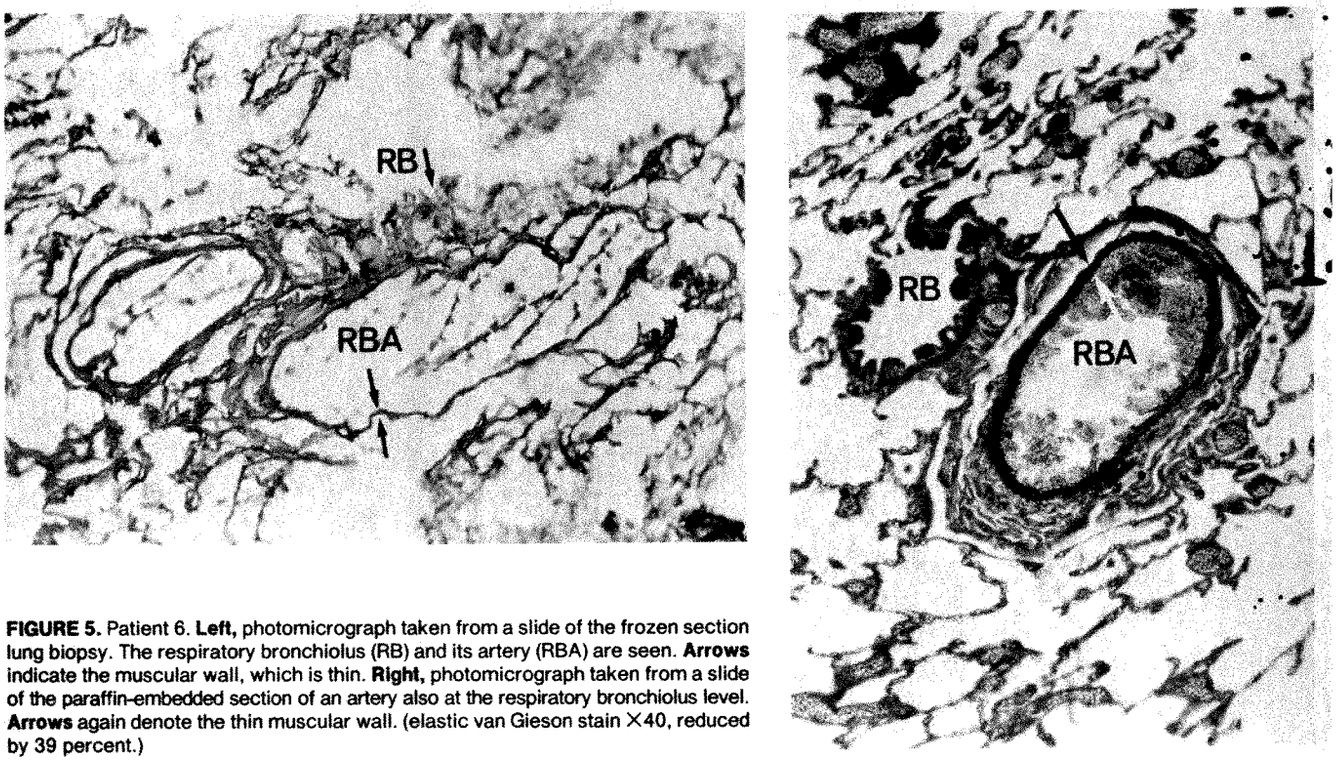

FIGURE 5. Patient 6. **Left,** photomicrograph taken from a slide of the frozen section lung biopsy. The respiratory bronchiolus (RB) and its artery (RBA) are seen. **Arrows** indicate the muscular wall, which is thin. **Right,** photomicrograph taken from a slide of the paraffin-embedded section of an artery also at the respiratory bronchiolus level. **Arrows** again denote the thin muscular wall. (elastic van Gieson stain ×40, reduced by 39 percent.)

pressure had decreased to less than half systemic level in spite of pulmonary venous obstruction, with a mean pulmonary arterial wedge pressure of 21 mm Hg. A further corrective procedure was performed and he awaits follow-up catheterization.

In spite of the large and tortuous aortopulmonary collateral vessels in the patient with tetralogy of Fallot and pulmonary atresia (Case 8), analysis of his lung biopsy tissue showed an essentially normal pulmonary vascular bed. Hence, stenoses of the collateral vessels were probably present although they were not obvious in the preoperative cineangiogram. A complete repair was performed in this patient with no untoward sequelae. Of the three remaining patients who had tricuspid atresia and were being considered for a Fontan procedure, one (Case 5) had only minimal pulmonary vascular changes of abnormal peripheral extension of muscle and another (Case 6) an essentially normal pulmonary vascular bed. In both of these patients, the proposed surgery was performed and in the postoperative period both had reduced levels of pulmonary arterial pressure (Fig. 5 and 7). The third patient (Case 7) had severe structural changes in the right lung with morphometric grade C and Heath-Edwards grade III to IV changes. The left lung biopsy tissue was small and, perhaps also because of the nature of the disease, included only four arteries. One of these vessels also had severe intimal hyperplasia. A Gortex central shunt was placed and the patient did well in the immediate postoperative period but later became progressively more cyanotic.

Discussion

Interpretation of preoperative hemodynamic data: Preoperative hemodynamic data as a basis for predicting postoperative outcome are sometimes very unsatisfactory. In some patients the sedative medication may decrease the level of pulmonary arterial pressure,

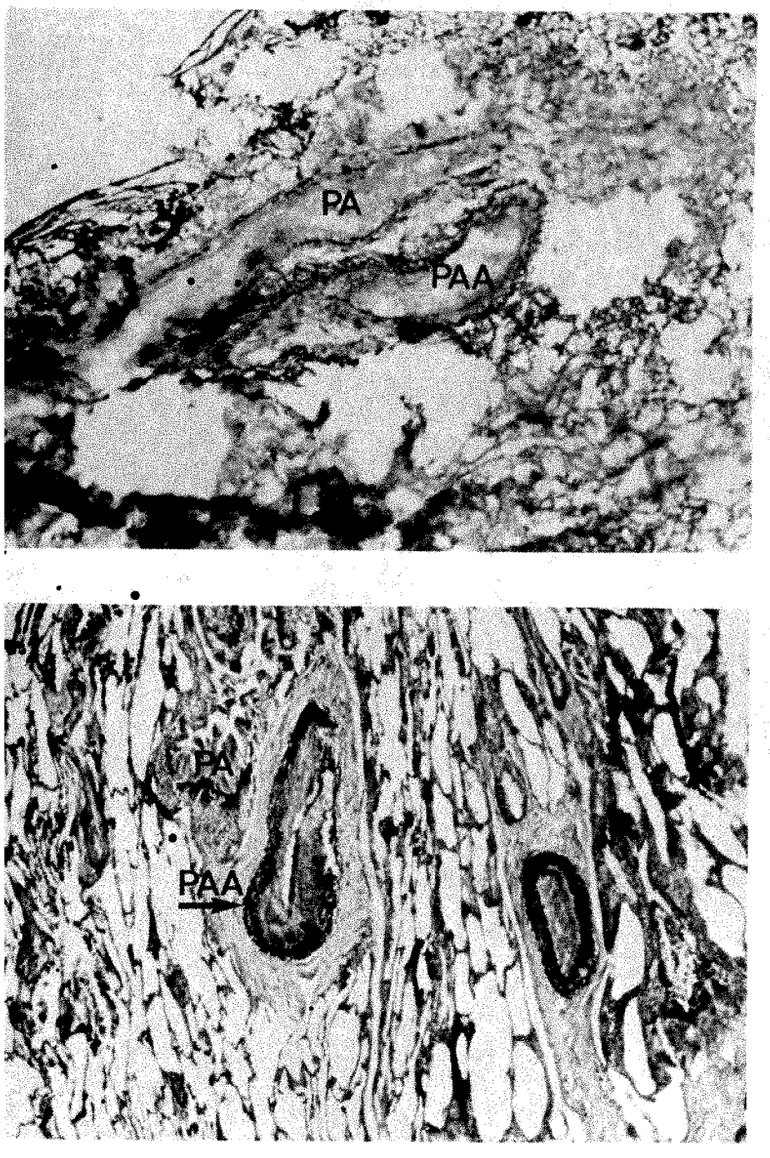

FIGURE 6. Patient 7. **Top,** photomicrograph taken from a slide of the frozen section lung biopsy. The preacinar airway (PA) and its artery (PAA) are seen, the latter with extensive intimal hyperplasia, disruption of the elastic laminae of the media, and dilatation. **Bottom,** a similar level vessel with similar features is seen on a photomicrograph taken from the slide of the paraffin-embedded section. (elastic van Gieson stain ×100, reduced by 39 percent.)

whereas in other patients, alveolar hypoxia, secondary either to upper airway obstruction or to pulmonary edema, may increase it.[18] Testing the reactivity of the pulmonary vascular bed to 100 percent oxygen can usually, but not always, detect the latter.

When the level of pulmonary arterial saturation is very high, as is characteristic in patients with d-transposition of the great arteries, the pulmonary blood flow is usually overestimated[11] and thus the level of pulmonary vascular resistance underestimated. In these patients, the contribution of the bronchial collateral circulation is difficult to assess and so the problem is compounded.

It is hazardous to place too much confidence in a measurement of reduced pulmonary arterial pressure when pulmonary blood flow is also decreased.[19] Mean pulmonary venous wedge pressures have been shown to correlate poorly with mean pulmonary arterial pressures[6] although agreement seems to be better in the lower ranges of pressure.

Morphology as an index of pulmonary vascular disease: Evaluating the morphologic state of the pulmonary vascular bed in lung biopsy tissue to assess the severity of pulmonary vascular disease is not new, but previous studies depended entirely on the Heath-Edwards grading of pulmonary vascular changes, which is helpful but has drawbacks. The more advanced structural changes (grade IV and higher) are uncommon in the first 2 years of life,[20–22] even in the presence of marked elevation of pulmonary vascular resistance. Also, the severe changes are not evenly distributed throughout the lung parenchyma, making it unreliable to assess only a small piece of biopsy tissue.[15] The system of morphometric analysis used here adds additional information at any age. It includes assessment of the earlier changes of abnormal growth and development of the small peripheral arteries that can be detected from the first days of life.[23] Moreover, these changes have been shown to be distributed uniformly throughout the lung unless there is localized abnormality of pulmonary blood flow.[24] In our group of patients biopsy tissue was taken from the lung of the systemic to pulmonary arterial shunt or from the lung periphery distal to large aortopulmonary collateral vessels. In one patient it was necessary to perform bilateral lung biopsies.

Morphometric assessment of the structure of the peripheral pulmonary arteries can be related to the degree of hemodynamic disturbance of the circulation. We now have a way to predict even minor degrees of elevation in pulmonary arterial pressure and resistance,[7] and this is particulary valuable if a patient is being considered for a Fontan-type surgical procedure.

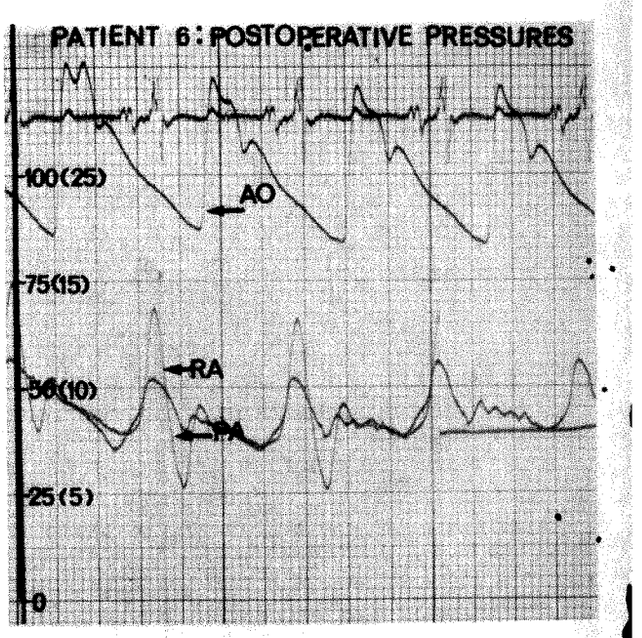

FIGURE 7. Patient 6. Postoperative pressure tracings. The electrocardiogram is at the **top.** The scale on the **left** shows calibrated values for aortic (AO) pressure, and in **parentheses** calibrated values for right atrial (RA) and pulmonary arterial (PA) pressure.

Acknowledgment

We acknowledge the support and guidance of Alexander S. Nadas, MD. We also express our gratitude to Tudor Williams and Eduardo Quintanilla, Donna Silva, Kathy Murray, Susan Aronovitz and Liz Cochary for technical assistance and to Margaret Wall, Nancy Warren, Terry McCarthy and Barbara Cesaro for assistance in preparation of this manuscript and its illustrations. We thank Dolly Hansen, MD and Carol Johnson, MD of the anesthesia department, the cardiovascular surgical residents and operating room nurses Jill Gorman, Gail Shauber, Kathy Moska, Sally Modest and Jodie Desilets for their cooperation and Carl Chipman for his help in gathering the postoperative data.

Ventricular Septal Defect in Infancy: Detection With Two Dimensional Echocardiography

JOHN P. CHEATHAM, MD
LARRY A. LATSON, MD
HOWARD P. GUTGESELL, MD, FACC

Houston, Texas

To determine the sensitivity and specificity of two dimensional echocardiography in detecting ventricular septal defect two dimensional echocardiograms were performed on 53 infants under 1 year of age. The diagnosis of ventricular septal defect was confirmed by cardiac catheterization in 27 patients; an intact ventricular septum was confirmed by catheterization in 18 and clinically in 8. Using a 35° mechanical sector scanner with a 3.5 megahertz transducer, we imaged the ventricular septum in the long axis and in a four chamber view (apical or subcostal, or both). Images were recorded on videotape and reviewed independently by two observers unaware of the diagnosis. Interobserver agreement was 94 percent. Among the 27 patients with a ventricular septal defect, the lesion was correctly identified in 20 (74 percent) and was undetected in 7 (3 of whom had a defect less than 4 mm in diameter, as determined by angiography). No defect less than 4 mm in diameter was detected. Among the 26 patients with an intact septum, a defect was correctly excluded in 23 (88 percent); a false positive diagnosis was made in 3. The apical and subcostal views demonstrated the greatest number of defects (20 of 20), but also gave the highest number of false positive diagnoses (3 of 3). The long axis view was helpful when positive, but showed only 9 of 20 of the defects.

In this study, two dimensional echocardiography detected approximately three fourths of ventricular septal defects large enough to warrant cardiac catheterization in the 1st year of life. False positive diagnoses were related to dropout of echoes in the membranous septum when imaged in the four chamber views.

Ventricular septal defect is a common cause of congestive heart failure in the 1st year of life. Although M mode echocardiography demonstrates the general features of left ventricular volume overload—enlargement of the left atrium and left ventricle—it fails to provide reliable visualization of the defect itself. Several studies have suggested that two dimensional echocardiography is useful in the diagnosis of ventricular septal defect. King et al.[1] described visualization of ventricular septal defect with B scan ultrasonography. Seward et al.[2] utilized real time, wide angle sector echocardiography to demonstrate ventricular septal defect in 22 infants and children. These studies included relatively few infants under 1 year of age, and because a control group was not included, they did not address the question of specificity of echocardiography in the diagnosis of ventricular septal defect. More recently Bierman and Williams,[3] described visualization of ventricular septal defect using real time wide angle sector echocardiography in patients similar to those in our current study. They reported 89 percent accuracy in the detection of ventricular septal defect and 98 percent accuracy in the localization of the defect in infants under 1 year of age.

The present study was undertaken to determine the sensitivity and specificity of real time two dimensional echocardiography in the detection of ventricular septal defect. Because the majority of patients initially evaluated for ventricular septal defect are small infants, we confined the study to patients under 1 year of age.

Methods

Study patients: Echocardiograms were obtained in 53 atients categorized into two groups on the basis of the presnce or absence of ventricular septal defect (Table I). Criteria or entry into the study were (1) a technically satisfactory two imensional echocardiogram with visualization of the venricular septum from at least two projections, and (2) confirmation of the presence of ventricular septal defect (by cardiac atheterization and angiography) or the absence of ventricular eptal defect (by either catheterization or clinical evaluaion).

The first group consisted of 27 infants with ventricular eptal defect, of whom 26 had a subcristal ventricular septal efect and 1 had a supracristal defect. Patients with an enocardial cushion defect and those with a muscular ventricular eptal defect were excluded from this study. The age of infants this group ranged from 1 day to 1 year (mean 4.7 months) nd their weight ranged from 2.7 to 10 kg (mean 4.7). Fifteen f these infants had only a ventricular septal defect; the reaining 12 had an associated defect: tetralogy of Fallot in 3; trial septal defect in 2, transposition of the great arteries in , double outlet right ventricle in 1 and valvular obstructive sions in 4.

The second group consisted of 26 infants with intact ventricular septum. This was confirmed by cardiac catheterizaon and angiography in 18 patients and clinically in 8. The ge of these patients ranged from 1 day to 1 year (mean 3.5 onths) and their weight ranged from 3.1 to 12.2 kg (mean .7). Of the 26 patients in this group, 14 had normal cardiac natomy; total anomalous pulmonary venous return, transosition of the great arteries and aortic stenosis were each resent in 3 patients, and coarctation of the aorta, atrial septal efect, and single atrium were each present in 1 patient. Of he six infants with normal cardiac anatomy undergoing cariac catheterization, five had cardiac arrhythmia and one had vascular ring.

Two dimensional echocardiography: Two dimensional hocardiograms were obtained using a model 513 Hoffrel 35° echanical sector scanner with a 3.5 megahertz transducer. he ventricular septum was imaged in a left parasternal long xis projection and in one or more four chamber views (apical r subcostal, or both). In the long axis view, the transducer was positioned at the third or fourth intercostal space, and the sector beam scanned the left ventricle from the apex to the aortic root (Fig. 1). The four chamber views were performed from the cardiac apex, the subxiphoid area and from points between these locations depending on where the optimal image of the ventricular septum could be obtained (Fig. 2 and 3). In this paper, we have used the term "subcostal" in referring to the projections obtained from beneath the ribs and xiphoid process in general, and the term "subxiphoid" when the image was obtained from the subxiphoid are in particular.

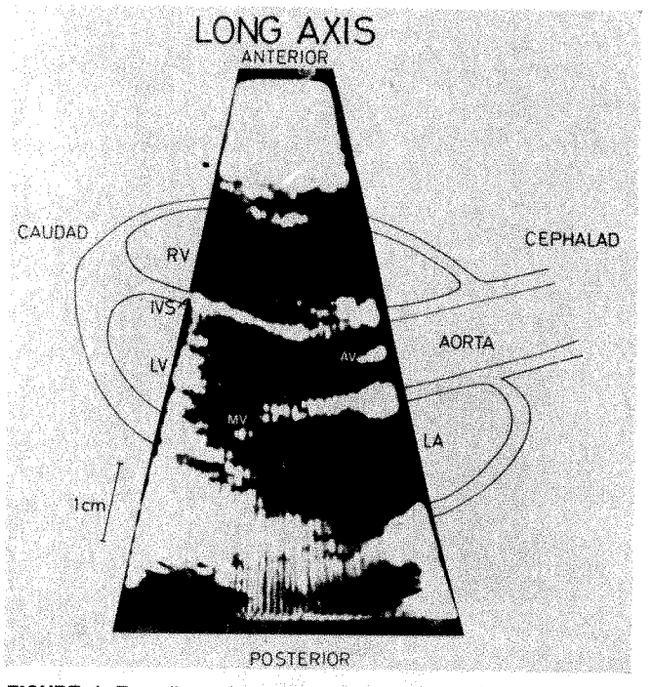

FIGURE 1. Two dimensional echocardiogram obtained using a left parasternal long axis projection in a normal infant. The figure is oriented with the subject's head to the observer's right and the feet to the left. The right (RV) and left ventricles (LV) are apparent, as well as the left atrium (LA), mitral valve (MV) and aortic valve (AV). The interventricular septum (IVS) is intact and continuous with the anterior aortic root.

The scans were permanently recorded on 0.5 inch (1.27 cm) videotape for future analysis. Subsequently, the videotapes were viewed and scored independently by two observers as to the presence or absence of ventricular septal defect. The tapes were viewed randomly without knowledge of the patient's identity or diagnosis. Interobserver agreement was 94 percent. In the case of disagreement, the decision of the more experienced observer was used in the final analysis of results.

ABLE I

o Dimensional Echocardiograms in Infants Less Than 1 ear of Age

Patients With Ventricular Septal Defect (n = 27)		Patients With Intact Ventricular Septum (n = 26)	
Subcristal	26	Catheterization	18
Supracristal	1	Clinically	8
ge 1 day–1 yr (mean 4.7 mo)		Age 1 day–1 yr (mean 3.5 mo)	
Veight 2.7–10 kg (mean 4.7)		Weight 3.1–12.2 kg (mean 4.7)

Results

Sensitivity of two dimensional echocardiography: Ventricular septal defect was correctly detected in 20 of the 27 patients with a proved defect. The diameter of the defect, as estimated from the angiograms, ranged from 4 to 12 mm (mean 7). In seven patients the defect was not visualized in the two dimensional echocardiogram. Thus, the sensitivity of echocardiography in the detection of ventricular septal defect in this group of patients was 74 percent. The defects undetected by echocardiography ranged from 3 to 10 mm in diameter, and three measured less than 4 mm in diameter. In the

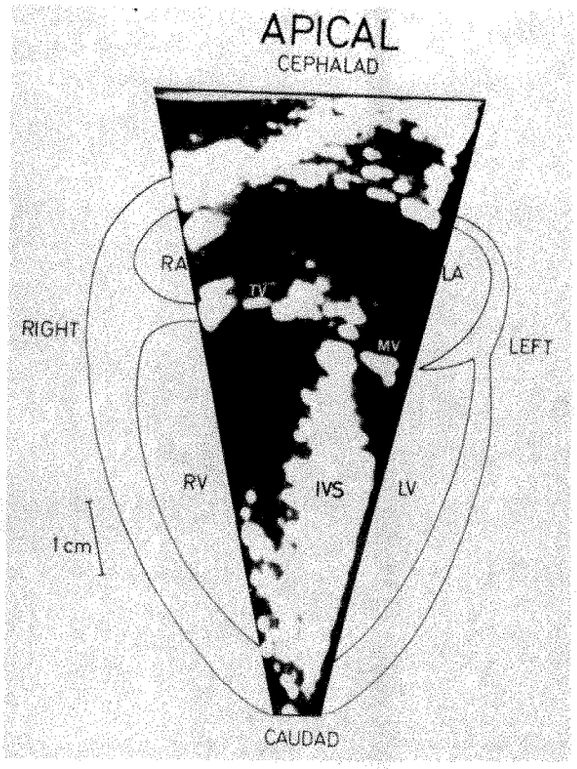

FIGURE 2. Two dimensional echocardiogram from the cardiac apex of a normal subject. The left-sided structures are to the observer's right, and the right-sided structures are to the left, similar to a four chamber angiographic projection. The right ventricle (RV), left ventricle (LV), right atrium (RA), left atrium (LA), tricuspid valve (TV) and mitral valve (MV) are visualized. The intact interventricular septum (IVS) is vertical in this projection, and runs parallel to the ultrasonic beam.

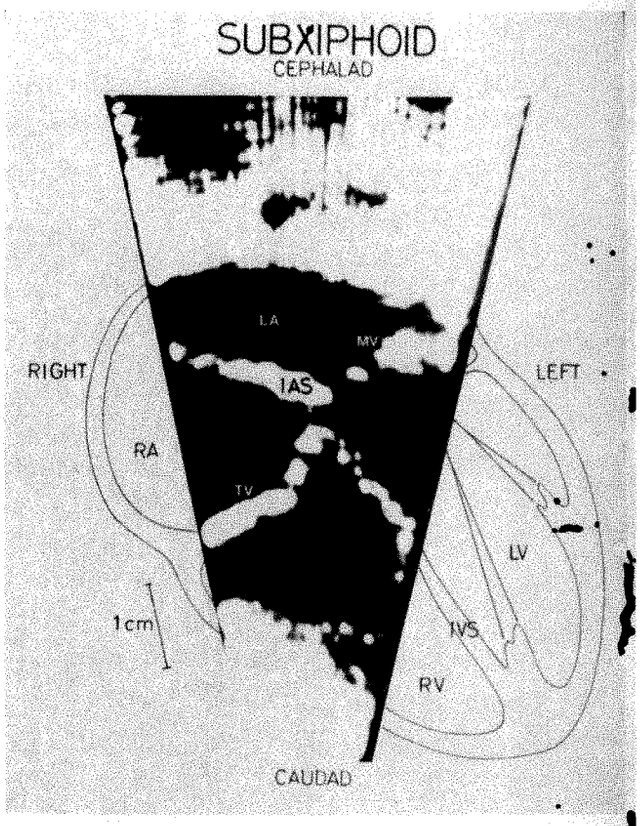

FIGURE 3. Normal two dimensional echocardiogram obtained from the subxiphoid area. The anatomy is similar to the apical projection and the structures are labeled accordingly. The intact interatrial septum (IAS) is imaged in this infant. The interventricular septum (IVS) is also intact and lies in a more transverse position than in the apical view. Abbreviations as in Figure 2.

subgroup of 15 patients with an isolated ventricular septal defect, the defect was correctly visualized in 11. The sensitivity within this subgroup was 73 percent. There was no significant difference in the sensitivity of detection of ventricular septal defect between patients with an isolated defect and those with an associated intracardiac defect.

Specificity of two dimensional echocardiography: Intact ventricular septum was correctly identified in 23 of the 26 infants with a proved intact septum. A false positive diagnosis of ventricular septal defect was made in three patients, two of whom had normal cardiac anatomy and one aortic stenosis. Thus, the specificity was 88 percent. In the 14 infants with normal cardiac anatomy, intact ventricular septum was correctly identified in 12 (specificity 86 percent). Thus, there was no significant difference in the specificity in visualization of intact ventricular septum between patients with various forms of congenital heart disease and those with normal intracardiac anatomy.

Long axis view: This projection demonstrated only 9 of the 20 defects that were detected with echocardiography in the 27 infants with ventricular septal defect (Fig. 4). Of the nine patients, eight had a subcristal ventricular septal defect, including the three patients with tetralogy of Fallot and the one infant with double

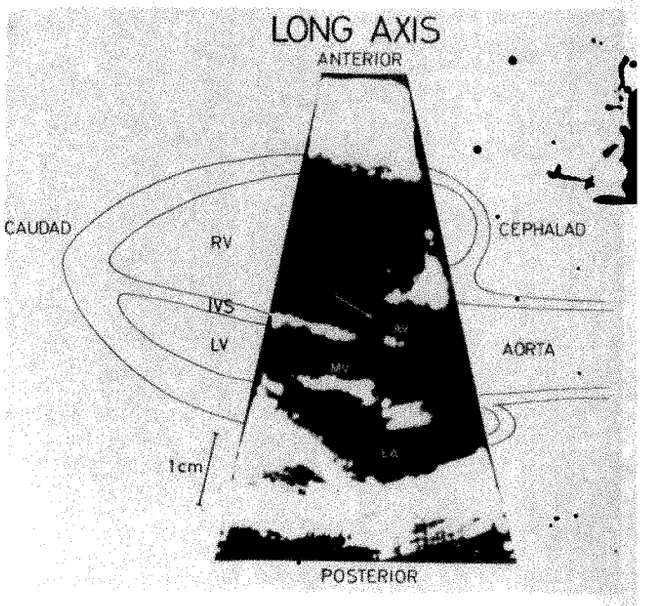

FIGURE 4. Two dimensional echocardiogram demonstrating the ventricular septal defect in a patient with tetralogy of Fallot (left parasternal long axis view). The defect (**arrow**) is seen immediately beneath the aortic root. Abbreviations as in Figure 1.

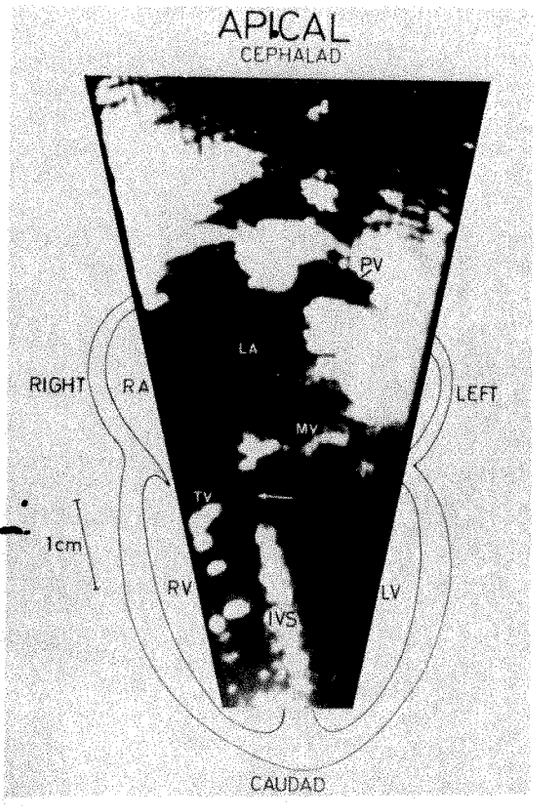
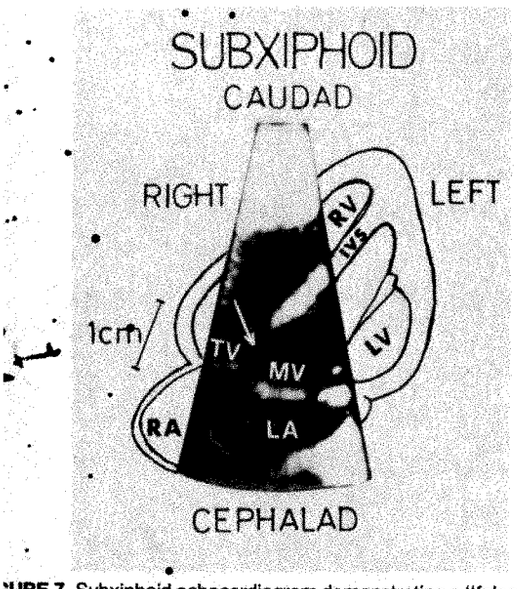


GURE 5. Apical four chamber view demonstrating the ventricular ptal defect (**arrow**) in an infant. A pulmonary vein (PV) is shown en- ing the left atrium (LA). Unidentified abbreviations as in Figure 2.



GURE 7. Subxiphoid echocardiogram demonstrating a "false positive" ıtricular septal defect. There appears to be a defect in the upper tion of the ventricular septum (**arrow**), immediately beneath the ınection of the mitral (MV) and tricuspid valve (TV) tissue. However, defect was identified at cardiac catheterization in this infant with ıgenital complete atrioventricular block. In this illustration, obtained fore modification of our ultrasonic equipment, the caudal and phalad orientation (but not the left-right relation) is reversed compared h that in the other illustrations. Thus, the apex is at the upper right ner of the figure. Unidentified abbreviations as in Figure 3.

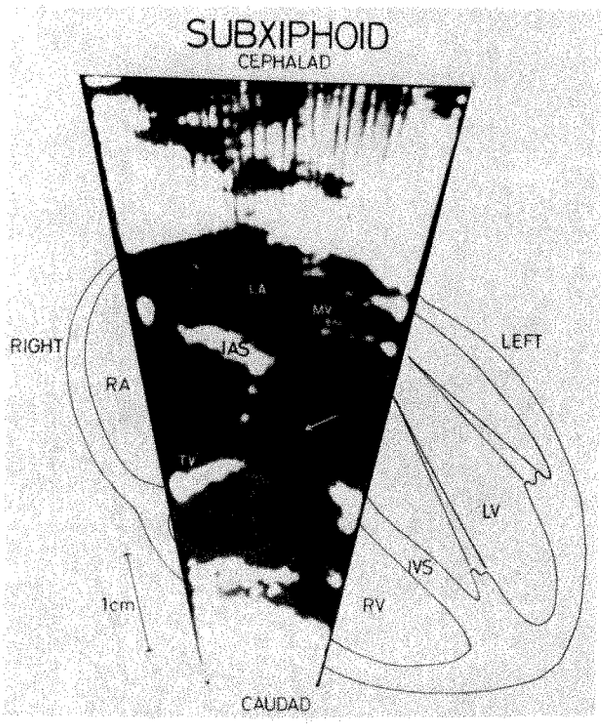


FIGURE 6. Subxiphoid view demonstrating a large ventricular septal defect (**arrow**) in a 3 month old infant. A secundum atrial septal defect was also demonstrated at cardiac catheterization and is seen here as a defect in the interatrial septum (IAS). Unidentified abbreviations as in Figure 3.

outlet right ventricle. The supracristal ventricular septal defect was also correctly diagnosed in this view. There was no false positive diagnosis using this projection.

Four chamber projections (apical and subcostal): These views demonstrated each of the 20 defects that were visualized in the 27 infants with ventricular septal defect (Fig. 5 and 6). However, these views also yielded the only three false positive diagnoses in the 26 patients with intact ventricular septum. In each of these infants, there appeared to be a defect in the upper portion of the ventricular septum, immediately below the connection of mitral and tricuspid valve tissue with the inferior portion of the atrial septum (Fig. 7).

Discussion

Factors affecting sensitivity of method: Two dimensional echocardiography appears to be useful in the diagnosis of ventricular septal defect in small infants. In the present study, we were able to demonstrate the defect in three fourths of the patients studied, with a false positive rate of 12 percent. It is apparent that several factors affect the sensitivity of two dimensional echocardiography in detection of ventricular septal defect:

1. *The resolution of the ultrasonic equipment.* In vitro studies in our laboratory[4] have indicated that a 3 mm diameter defect in a strip of canine myocardium is

the smallest size that can be consistently visualized with our ultrasound equipment. In the present study, the smallest defect correctly identified was 4 mm in diameter, and defects of 3.0, 3.0 and 3.5 mm were undetected. Improvements in resolution may be possible with transducers of higher frequency.

2. *The anatomic location of the defect.* A defect in the anterior portion of the septum, as in tetralogy of Fallot, is easily demonstrated in the long axis projection. In addition, a false positive diagnosis is uncommon in this view. The four chamber views (apical and subcostal) appear particularly helpful in the detection of subcristal ventricular septal defect without an overriding aorta. However, in these projections, the ultrasonic beam is in a parallel rather than in a perpendicular orientation with relation to the septum, and "dropout" of nonreflected echoes is more likely to occur. Thus, these projections were subject to false positive diagnoses of ventricular septal defect.

3. *The composition of the study group.* In a study group consisting of patients with tetralogy of Fallot or infants with a large ventricular septal defect, the sensitivity and specificity of two dimensional echocardiography may approach 100 percent. Conversely, among patients with a ventricular septal defect less than 3 mm in diameter, the sensitivity will no doubt be lower.

4. *Skill and bias of the ultrasonographer.* Unfortunately, interpretation of two dimensional echocardiograms is partially subjective. A ventricular septal defect may be undetected if appropriate areas of the septum are not imaged. Likewise, it is more likely to be diagnosed by a physician-ultrasonographer aware of clinical findings such as congestive heart failure or a holosystolic murmur. In the present study, we attempted to eliminate the latter source of bias by interpreting the videotapes without knowledge of the patient's identity or clinical status.

Enhancement of diagnostic accuracy: Although one view may appear more sensitive or specific than another, we recommend that all projections be utilized in evaluating the infant with suspected ventricular septal defect. In addition to the views used in this study, Bierman and Williams[3] recently utilized a subxiphoid sagittal projection with excellent results in the detection and localization of ventricular septal defect in infants. Muscular ventricular septal defects are difficult to detect with any of the customary projections.[2,3] Pulsed Doppler echocardiography may assist in the detection of defects in the muscular portion of the septum,[5] and may be particularly useful when combined with two dimensional echocardiography.

Clinical implications: Two dimensional echocardiography is a useful adjunct to the noninvasive evaluation of the child with possible ventricular septal defect. It appears most useful in cases in which a large defect may be masked by the presence of other cardiac anomalies (for example, transposition of the great arteries). However, the technique must be used in conjunction with other clinical studies and with the realization that false positive and false negative diagnoses occur. In particular, the technique has limited value in evaluation of the child whose ventricular septal defect is small and thus possibly below the limits of resolution of existing ultrasonic equipment.

Acknowledgment

We acknowledge the assistance of Paula Feinman in performing the echocardiograms, of Candy Killebrew in preparing the manuscript, and of Americo Simonelli in preparing the illustrations.

Postnatal Endocardial Fibroelastosis of the Valve of the Foramen Ovale

ROVER M. HUTCHINS, MD
. WILLIAM MOORE, MD, PhD*
)CELYN F. JONES
TEPHEN T. MILLER, MD

altimore, Maryland

The valve of the foramen ovale of the heart changes at birth from a prenatal shunting device for the transseptal flow of systemic venous return to a postnatal active barrier to backflow of left atrial blood at higher pressure. To investigate the morphologic response to this functional change in the valve of the foramen ovale, we examined 200 hearts from embryos, fetuses and autopsy patients spanning over a millionfold range of heart weights (0.001 to 1,230 g). The relation of valve thickness to log heart weight was studied by a stepwise linear regression procedure that fitted the data to two linear regressions, one including observations made before birth and the other including observations made after birth. Analysis of variance tables demonstrated that the data are significantly better explained ($p < 0.001$) by two linear regressions that abruptly separate from one another at the time of birth than by a single linear regression. Histologic study showed that the prenatal valve consists of a thin myocardial layer with delicate endocardium. The postnatal thickening of the valve tissue occurs mainly by fibroelastotic thickening of the endocardium. The endocardial fibroelastosis of the valve develops after it closes and becomes a component of the left atrial wall. The observations support the concept that fibroelastosis is a nonspecific response of the lining of the cardiovascular system to increased mural tension.

The pathogenesis of endocardial fibroelastosis has been controversial. Its occurrence had been variously considered a reaction to inflammation, a congenital defect, the result of lymphatic obstruction, a response to hypoxia or the consequence of a metabolic defect, but most of these notions have been discredited.[1] Alternatively, the variety and nature of the settings in which fibroelastosis is observed have led to the concept that it may be a nonspecific stereotyped response of the cardiovascular lining layers to states of increased mural tension.[2–4]

Normal atrial endocardium has a histologic structure that is identical to the fibroelastosis found in pathologic states. In this study we examined the endocardial changes that occur on that component of the septum primum that forms the valve of the foramen ovale. The orifice of the foramen ovale of the heart is surrounded by the tissues of the atrial septum secundum. In the normal developing heart before birth, this orifice is guarded on its left side by a portion of the atrial septum primum, the valve of the foramen ovale. After birth there is functional closure of the valve as the pressure in the left atrium increases relative to that in the right. In changing from a passive structure in the transseptal bloodstream into a barrier of the orifice of the foramen ovale, the valve becomes subject to the tension that acts on the atrial wall. The principal determinants of mural tension at any point are intracavitary pressure and the wall curvature.[5]

To evaluate the nature of the postnatal thickening of the valve of the foramen ovale, human hearts spanning over a millionfold range of heart weights were examined. The relations between age, heart weight, foramen patency, thickness of the valve and histologic structure were studied.

Methods

Preparation of hearts: To provide a wide range of material, human hearts from several sources were examined. Seventeen normal human embryos and fetuses ranging from stage 14 to 45 mm crown-rump length had been prepared by serial histologic sections. Details of the preparation, staining and staging of the embryos and three fetuses have previously been given.[6] Heart weights for these specimens were estimated from the size of the heart as seen on sections, and ranged from 0.001 to 0.08 g.[7] For these specimens, the thickness of the valve of the foramen ovale was measured from the histologic sections using a calibrated micrometer in the microscope ocular. Eleven fetuses of gestational ages 21 to 39 weeks were dissected, and heart weight was determined directly. The thickness of the valve of the foramen ovale was determined as before on histologic sections of the heart. The gestational age of the fetuses was estimated from the body size.[8]

The hearts of 26 stillborns and newborns up to 30 days of age, 18 infants up to 1 year of age and 28 children 1 to 15 years of age examined at autopsy at The Johns Hopkins Hospital were studied. The thickness of the valve of the foramen ovale was determined by direct measurement on the specimen using a micrometer calibrated to 0.01 millimeter. The diameter of the patent orifice, if present, was measured with an aluminum cone calibrated for millimeters of diameter. Blocks were taken from the interatrial septum of each specimen and processed routinely, sectioned at 5 μ, and examined after hematoxylin-eosin and Verhoeff-van Gieson elastic staining.

The hearts of 100 adults that had been examined after postmortem coronary arteriography and fixation in a distended state[9] were also studied as described. Among the 100 patients; 50 had no clinical or pathologic evidence of cardiac disease; the remaining 50 had cardiac enlargement secondary to a variety of disorders.

The patency of the foramen ovale was determined in all cases. When possible the diameter of its orifice was measured.

Data analysis: The valve thickness measurements were summarized both by ordinary descriptive statistics (mean ± standard error) and by a stepwise linear regression technique designed to highlight abrupt changes in the pattern of valve growth that might take place at birth. The valve thickness data were fitted initially to a simple linear regression with log age as the independent variable. The data were then partitioned into two subsets: one containing observations up to and including birth, and the other containing observations taken after birth. Two pairs of least squares linear regressions were fitted to these partitioned data. The first pair of regressions was constrained to have the same slope but arbitrary intercepts. The second pair was not constrained: Both slopes and intercepts were arbitrary. An analysis of variance (ANOVA) table was prepared in the usual manner.[10] The presence of a significant F value for the constrained regression pair would suggest that two parallel linear regressions better describe the data than does a single regression. A significant F value for the unconstrained regression pair would suggest that two arbitrary linear regressions better describe the data than do two parallel regressions.

Results

Histology: The principal findings in the various groups of hearts are given in Table I. Histologically (Fig. 1 and 2) the valve of the foramen ovale in the embryo and fetus is composed of a few cardiac muscle cells and two thin layers of endocardial tissue. At birth the muscle content of the valve has increased and is responsible for almost the entire thickness of the valve. The endocardial tissue at this time is a delicate layer. After birth, there is a dramatic increase in the thickness of the endocardium, which produces the majority of the increased thickness of the valve. This endocardial proliferation occurs on both sides of the valve and is characterized by formation of fibroelastotic laminae. There is also an increase in the myocardial component of the valve as the result of enlargement of cardiac muscle cells.

TABLE I
Heart Weight, Valve Thickness and Foramen Ovale Patency by Age Groups

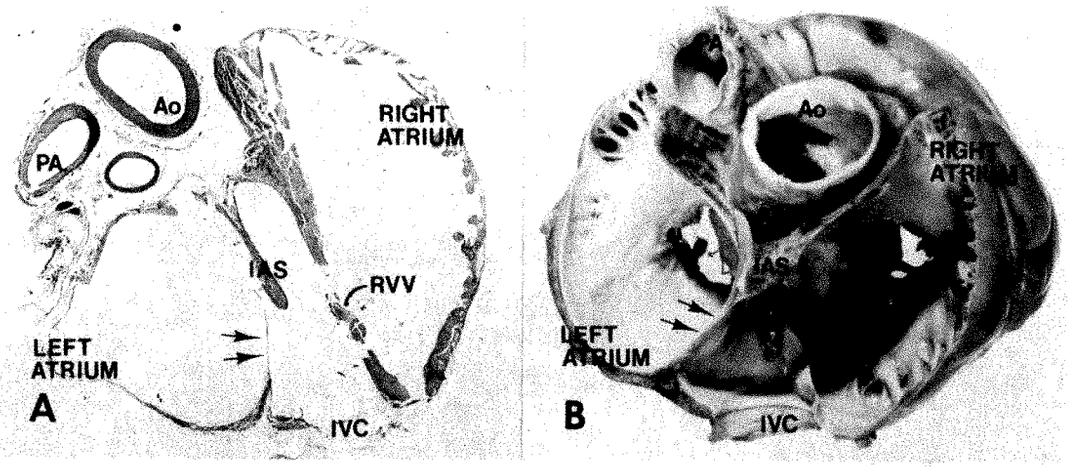
	n	Heart Weight* (g)	Thickness* of Valve of Foramen Ovale (mm)	Patent Foramen Ovale n	Patent Foramen Ovale (%)
Embryos and fetuses (8 to 20 weeks)	17	0.8 ± 0.2	0.02 ± 0.002	17	(100)
Late fetuses (21 to 39 weeks)	11	8.3 ± 2.2	0.21 ± 0.04	11	(100)
Newborns (birth to 1 month)	26	13 ± 1.2	0.33 ± 0.03	13	(100)
Infants (1 month to 1 year)	18	40 ± 4.8	1.33 ± 0.09	10	(56)
Children (1 to 15 years)	28	131 ± 18	1.10 ± 0.06	4	(14)
Adults, normal hearts (over 15 years)	50	292 ± 8.1	1.18 ± 0.05	11	(22)
Adults, hypertrophy (over 15 years)	50	694 ± 35	1.15 ± 0.06	5	(10)
Total	200	250 ± 21	0.91 ± 0.04	84	(42)

* Values expressed as mean ± standard error of the mean.

Relation of thickness of valve of foramen ovale to heart weight (Fig. 3): During intrauterine life, which corresponds to a heart weight of less than 15 g, there is a slight and progressive increase in valve thickness, which corresponds to the increasing heart weight of fetal growth. During the increase in heart weight from 15 to 40 g, there is a dramatic increase in valve thickness. The range of heart weights between 15 and 40 g corresponds to the 1st months of life and the rapid increase in valve thickness in this weight distribution corresponds to the increase observed in postnatal life.

Relation between thickness of valve of foramen ovale and age (Fig. 4): There is a slight and gradual increase in thickness during the last 5 months of gestation. The average thickness of the valve at birth is 0.33 mm. Beginning immediately with birth and continuing until 6 months of age, there is a very rapid increase in the amount of valve tissue. After 6 months of age there is some variability in valve thickness, but there is no apparent increase in valve tissue after the initial rapid increase, and the thickness of the valve increases only slightly throughout life.

Valve thickness as a function of heart weight and age: Table II shows the analysis of variance table for the



IGURE 1. **A**, histologic section through the atria of the heart of a fetus. The valve (**arrows**) allows blood to pass through the patent foramen ovale the interatrial septum (IAS) from the right to the left atrium. The right venous valve (RVV) or the valve of the inferior vena cava (IVC) tends to rect venous return toward the septum (Verhoeff-van Gieson elastic stain X9, reduced by 33 percent). **B**, adult heart, sectioned as in **A**, and viewed om the atrial aspect. The valve of the foramen ovale (**arrows**) is an integral structural component of the interatrial septum. Ao = aorta; PA = pulmonary tery.

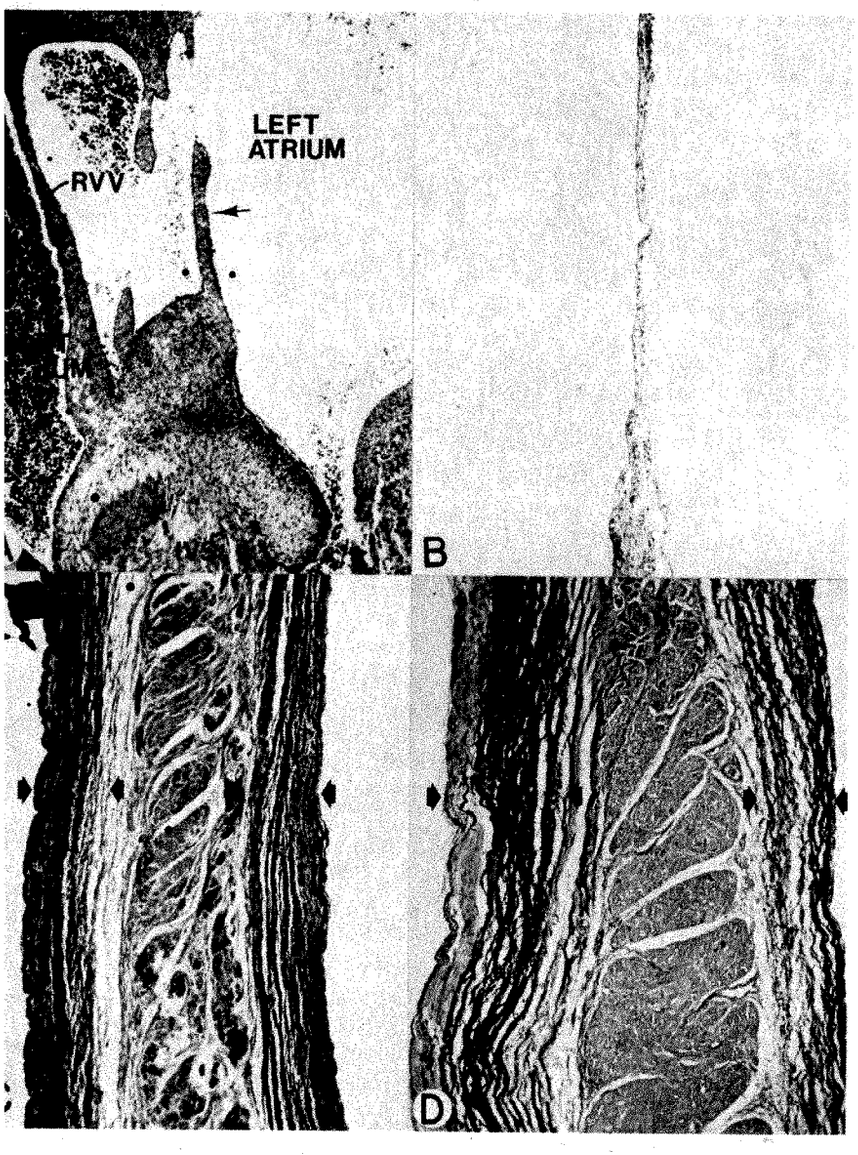


FIGURE 2. Valve of the foramen ovale at different stages of development. In the embryo (**A**) and fetus (**B**) the valve (**arrow**) is delicate with a thin endocardial layer and a few myocytes. In a child (**C**) and adult (**D**) the valve has become a component of the atrial wall and has endocardial fibroelastosis (**between arrows**) on both sides as well as a thicker myocardial layer. IVS = interventricular septum. (All Verhoeff-van Gieson elastic stain X90, reduced by 33 percent.)

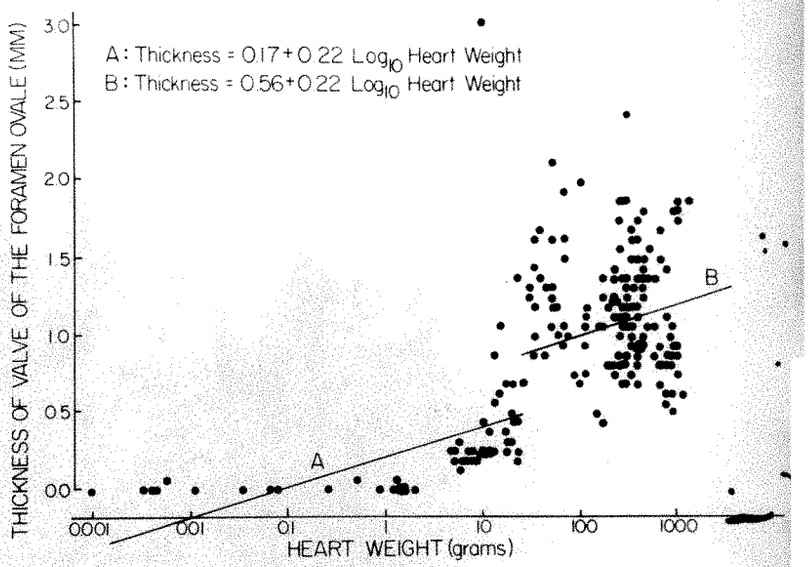

FIGURE 3. Thickness of the valve of the foramen ovale as a function of log heart weight. Slope of the double linear regression equation, identical for the prenatal subset (**A**) and the postnatal subset (**B**), is significant ($p < 0.001$). The intercept difference for prenatal and postnatal subsets is significant ($p < 0.005$).

regression of valve thickness as a function of log age, partitioned into prenatal and postnatal subsets. The regression consisting of a separate linear regression for each subset, constrained to the same slope, fitted significantly better ($p < 0.001$) than either a single linear regression (no partitioning) or no regression (that is, zero slope). However, when the separate linear regressions were allowed to have distinct slopes, no significant additional variance was explained. The common slope of this least squares fit was 0.22, with an intercept of −0.18 for the prenatal subset and 0.43 (= −0.18 + 0.61) for the postnatal subset (Fig. 4). Both regression coefficients (slope coefficient with respect to age and subset coefficient) were highly significant ($p < 0.001$), and the standard errors were small with respect to their corresponding coefficients. Similar results were obtained with log heart weight as the independent variable. These

Log_{10} age	0.22	0.04	30.61	<0.001
Subset (prenatal = 0, postnatal = 1)	0.61	0.10	34.81	<0.001

* Arbitrary intercepts and identical slopes for prenatal and postnatal subsets. Arbitrary slopes did not explain significant additional variance.

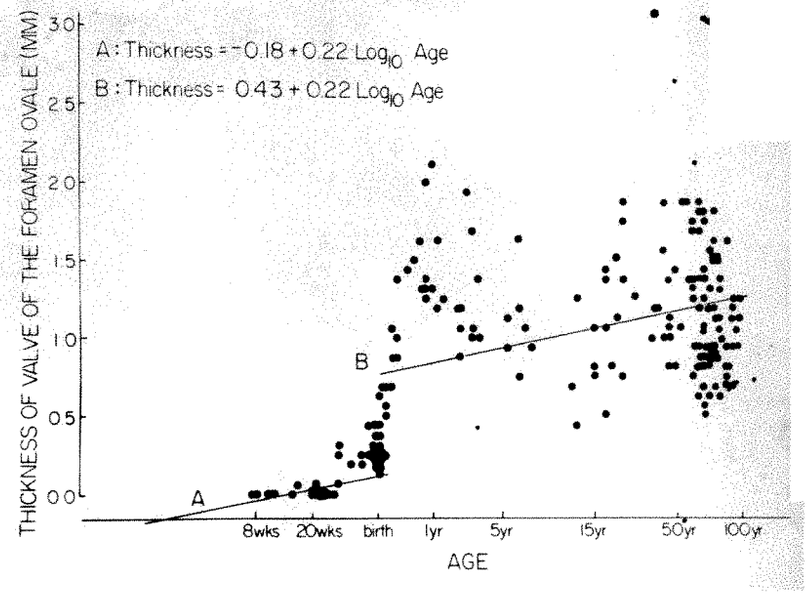

FIGURE 4. Thickness of the valve of the foramen ovale as a function of log age in weeks post-conception. The slope of the double linear regression equations, identical for the prenatal subset (**A**) and the postnatal subset (**B**), is significant ($p < 0.001$). The intercept difference for the prenatal and postnatal subsets is significant ($p < 0.001$).

findings demonstrate that the thickness of the valve of the foramen ovale increases slowly until birth, abruptly thickens in the newborn period, and then returns to a pattern of slow, steady increase.

Diameter and patency of foramen ovale: From 1 to 15 g of heart weight the diameter of the foramen ovale increases steadily from 1 to about 4 mm in diameter. For heart weights of 15 to 20 g, which correspond to heart weights at birth after 9 months' gestation, the mean diameter of the foramen ovale is 4.3 mm (range 3 to 6 mm). The earliest instance of complete anatomic closure occurred in a heart weighing 28 g from a 7 month old infant. The majority of the foramens were obliterated after 40 g of heart weight. In those specimens in which age was greater than 15 years, probe-patency of the foramen was demonstrated in 16 percent. There was no apparent association with age or heart weight. All specimens demonstrated sufficient valve tissue to prevent left to right intraatrial shunting of blood.

Discussion

Histology: The valve of the foramen ovale before birth is composed of a sheet of cardiac muscle cells and thin layers of endocardial tissue. At birth the muscle content has increased and accounts for most of the thickness of the valve, but the endocardial tissue remains as two thin layers. A few elastic fibers have appeared between the endothelial and collagen layers of the endocardium. Soon after birth the valve increases abruptly in thickness ($p < 0.001$). A prominent endocardial elastic layer develops, with an inner part composed of this network of fine elastic fibers and an outer part composed of thicker elastic fibers and fine collagen fibers. This dramatic growth of fibroelastic tissue results in a thick endocardium by the end of the 1st year. In the adult heart, subsequent changes in endocardial structure are minor and appear to be uninfluenced by cardiac hypertrophy or patency of the foramen ovale. Thus, the valve of the foramen ovale in the adult heart is formed by central muscle bundles and two thick endocardial surfaces. The thick endocardium is morphologically identical to the fibroelastosis found in the cardiovascular system in various disease states.

Endocardial fibroelastosis as a response to mural tension: Endocardial fibroelastosis has been associated with such diverse conditions as hypoplastic left heart syndrome, anomalous origin of the left coronary artery from the pulmonary trunk, idiopathic endocardial fibroelastosis, glycogen storage disease, coarctation of the aorta and myocardial infarction. Hypotheses on the origin of endocardial fibroelastosis have included hypoxia, lymphatic obstruction, increased cavity pressure, fibrin deposition or combinations of these factors.[1] Black-Schaffer[2] first suggested that idiopathic endocardial fibroelastosis is a response to the dilatation of the left ventricular chamber. Other morphologic evidence supports this concept that endocardial fibroelastosis is a nonspecific response to increased mural tension,[3,4] and intimal fibroelastosis in blood vessels has been similarly interpreted.[11] The magnitude of this mural tension, and the amount of fibroelastic connective tissue formed, appears to correlate with decreased curvature of the cavity and increased intracavitary pressure, consistent with the Laplace relation.[5] With postnatal closure of the foramen ovale on establishment of an increased pulmonary circulation, the valve becomes a component of the atrial wall and becomes subject to the same mural tension existing in other portions of the atrium. The valve usually becomes curved concave to the left atrium (Fig. 1B), probably because of the relatively higher pressure normally found on the left side of the heart. Presumably tension would be applied to the full thickness of the valve. No relation was discovered between patency of the foramen ovale and thickness or any histologic feature of the valve. The incidence of patency of the foramen ovale found in this group of hearts was somewhat less than that reported by others in the adult heart.[12–14]

In conclusion, examination of the valve of the foramen ovale in 200 hearts over a wide range of age and heart size showed a highly significant increase in valve thickness in the postnatal period ($p < 0.001$) caused by the development of endocardial fibroelastosis and an increase in myocardium in the valve. The increase in thickness occurs after the postnatal conversion of the valve from a free structure in the bloodstream to a tension-sustaining component of the atrial wall. The observations support the concept that fibroelastosis is a nonspecific response of the cardiovascular lining layers to increased mural tension.

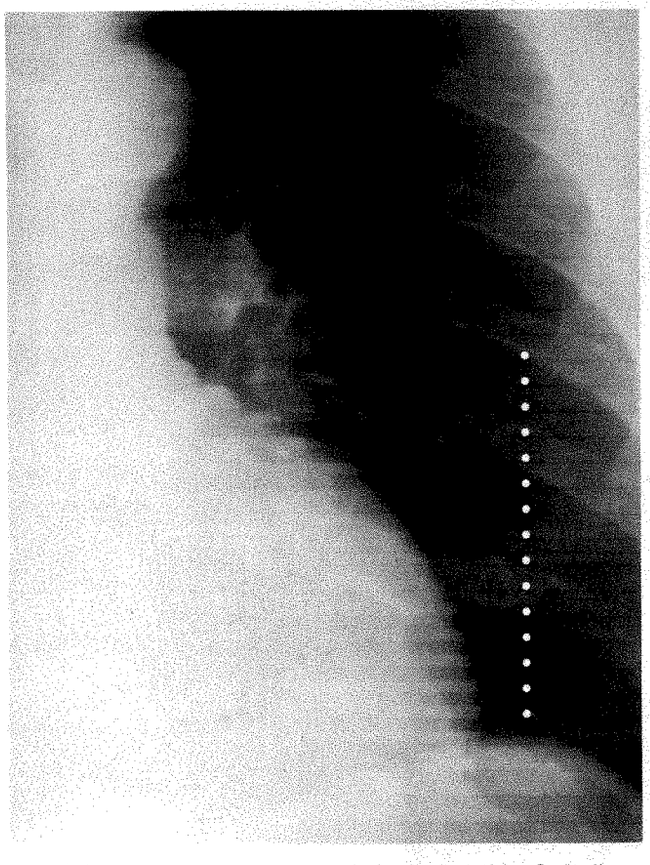
Now you can see coronary artery disease. In a routine X-ray.



This IRS x-ray shows an asynergistic contraction. Systolic strips are marked in this image with white dots, clearly illustrating normal motion in the basal segment, hypokinesis in the lateral wall and paradoxical motion in the apex.

Now there is a simple, accurate technique for observing and quantifying ventricular wall motion abnormalities: the InterGated™ Radiography System (IRS), from Brattle.

IRS works with existing x-ray equipment, involves no major investment, and requires no special training to use.

HOW DOES IT WORK?

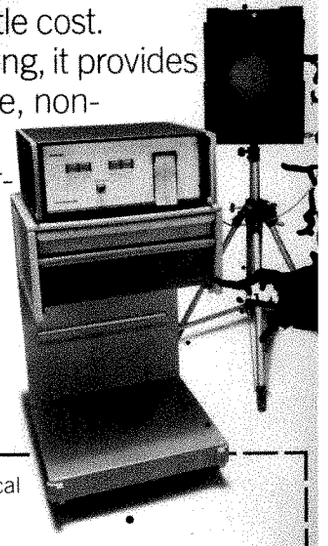
Brattle's IRS produces a serrated cardiac image showing heart motion. The IRS is able to capture the heart at end diastole and end systole during a single cardiac cycle by using ECG-gating. The result is a precise image that can be used to measure and evaluate abnormal heart wall motion, valvular defects and shunts.

Unlike Roentgenkymography, IRS is highly sensitive, highly specific and exposes the patient to no additional radiation.

WHERE IS IT USED?

Brattle's IRS is already in use in hospitals and doctors' offices, where it can dramatically increase the information content of routine x-rays at very little cost.

In addition to screening, it provides physicians with a simple, non-invasive method for monitoring patients during follow-up examination or ECG stress testing.



WANT TO LEARN MORE?

☐ Please send reprints on clinical use of Brattle's InterGated™ Radiography System.

☐ Please contact me to show me some interesting x-rays.

SUSTAINED RELEASE
Procan™ SR
(PROCAINAMIDE
HYDROCHLORIDE TABLETS)
for selected cardiac dysrhythmias
administered half as often
as conventional oral procainamide
can be used concomitantly with digoxin without significant change in digoxin serum levels[1]
q6h dosage maintains procainamide blood levels all day and all night
at steady-state, plasma levels demonstrated the bioequivalence of Procan SR given q6h to that of an equal total daily dosage of conventional procainamide given q3h[2]
Procan SR...the original
sustained release oral procainamide
PARKE-DAVIS

Procan™ SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE
Before prescribing, please see full prescribing information.
A Brief Summary follows:

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient re-evaluated because asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney diseases, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome. Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patie receiving maintenance procainamide therapy.

ADVERSE REACTIONS: Hypotension following oral administrati is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reporte (see PRECAUTIONS). Reactions consisting of fever and chills hav also been reported, including a case with fever and chills plus nau sea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses c the drug. Bitter taste, diarrhea, weakness, mental depression, gidd ness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

Agranulocytosis has occasionally followed the repeated use of t drug, and deaths have occurred. Therefore, routine blood counts a advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tra infection. If any of these should occur, and leukocyte counts indica cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride tablets) are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every hours instead of the more frequent every-three-hour dosing interva required for standard preparations of oral procainamide hydrochlo ride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamic hydrochloride is recommended until the tachycardia is interrupted the limit of tolerance is reached. Maintenance may then be continu with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of stan dard procainamide hydrochloride followed thereafter by a total dai dosage of 50 mg/kg of body weight given at three-hour intervals. The suggested oral dosage for premature ventricular contractions 50 mg/kg of body weight daily given in divided doses at three-hou intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg c body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0. g every six hours; patients weighing between 55 and 91 kg (120 an 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (2 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatme with standard procainamide hydrochloride is recommended until th arrhythmia is interrupted or the limit of tolerance is reached. Mainte nance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Star dard procainamide hydrochloride may then be given at a dosage o 0.5 g to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every s hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: N 0071-0202 Procan SR 250 mg. Each sustained release tablet contains 250 mg procainamide hydrochloride. Available in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 10 tablets each).

N 0071-0204 Procan SR 500 mg. Each sustained-release, scored tablet contains 500 mg procainamide hydrochloride. Available in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 1 tablets each).

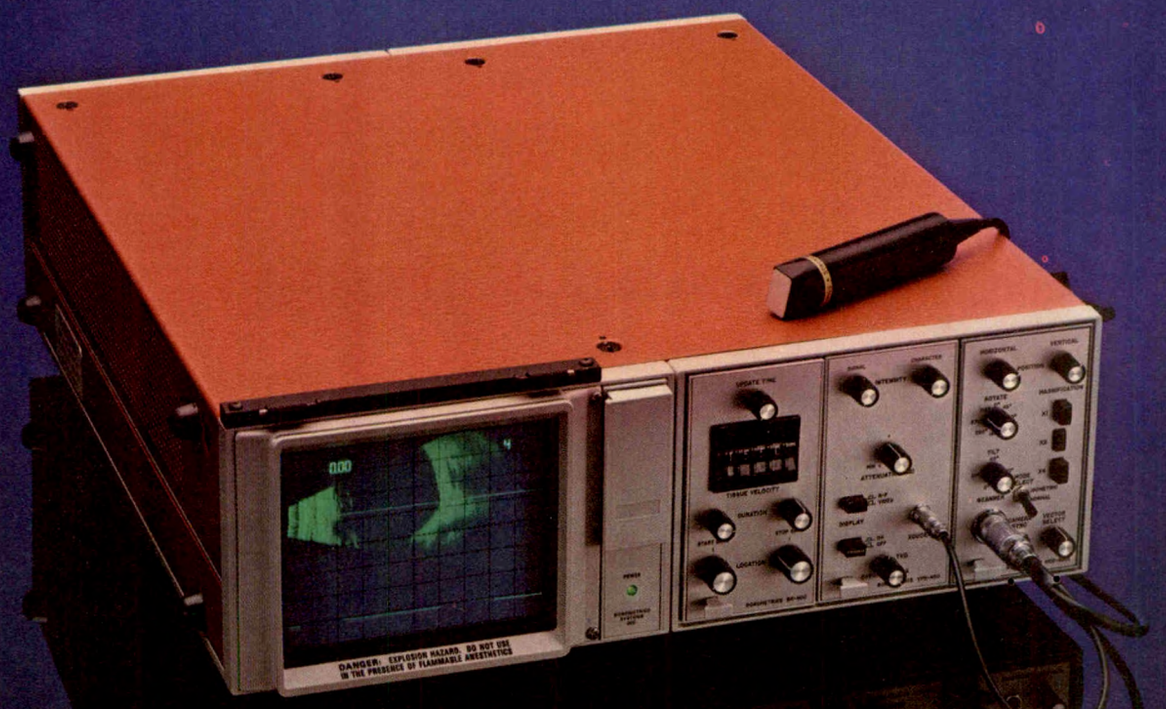
Sonometrics' Ocuscan™

More Quality, Portability and Value... More of Everything you want in a Small Parts Scanner



The Sonometrics' Ocuscan is the ideal ultrasonic instrument for efficient, accurate diagnosis and documentation of small organs. Highly portable, the Ocuscan can be used for the carotid artery, thyroid, breast, scrotum and ophthalmic imaging.

For the Radiologist or Diagnostician looking for an advanced modular scanning system the Ocuscan fills the bill with options like, stored A and B-Scan with Digital Scan Converter which is compatible with any VTR for future reference and documentation; and features like extended grey scale; a large range of transducer frequencies with soft membrane heads, exceptional resolution and easy to interpret real-time images, synchronous single-frame photography and Vector Scan™ for simultaneous A and B-scan presentations.

The Ocuscan includes complete installation and training and is backed by the complete technical resources of Sonometrics, the first and leading company in Ophthalmic Ultrasound.

For more information call toll free (800) 223-0412. In N.Y. State call (212) 765-8205 or mail the coupon enclosed.

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, M.D., FACC, Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

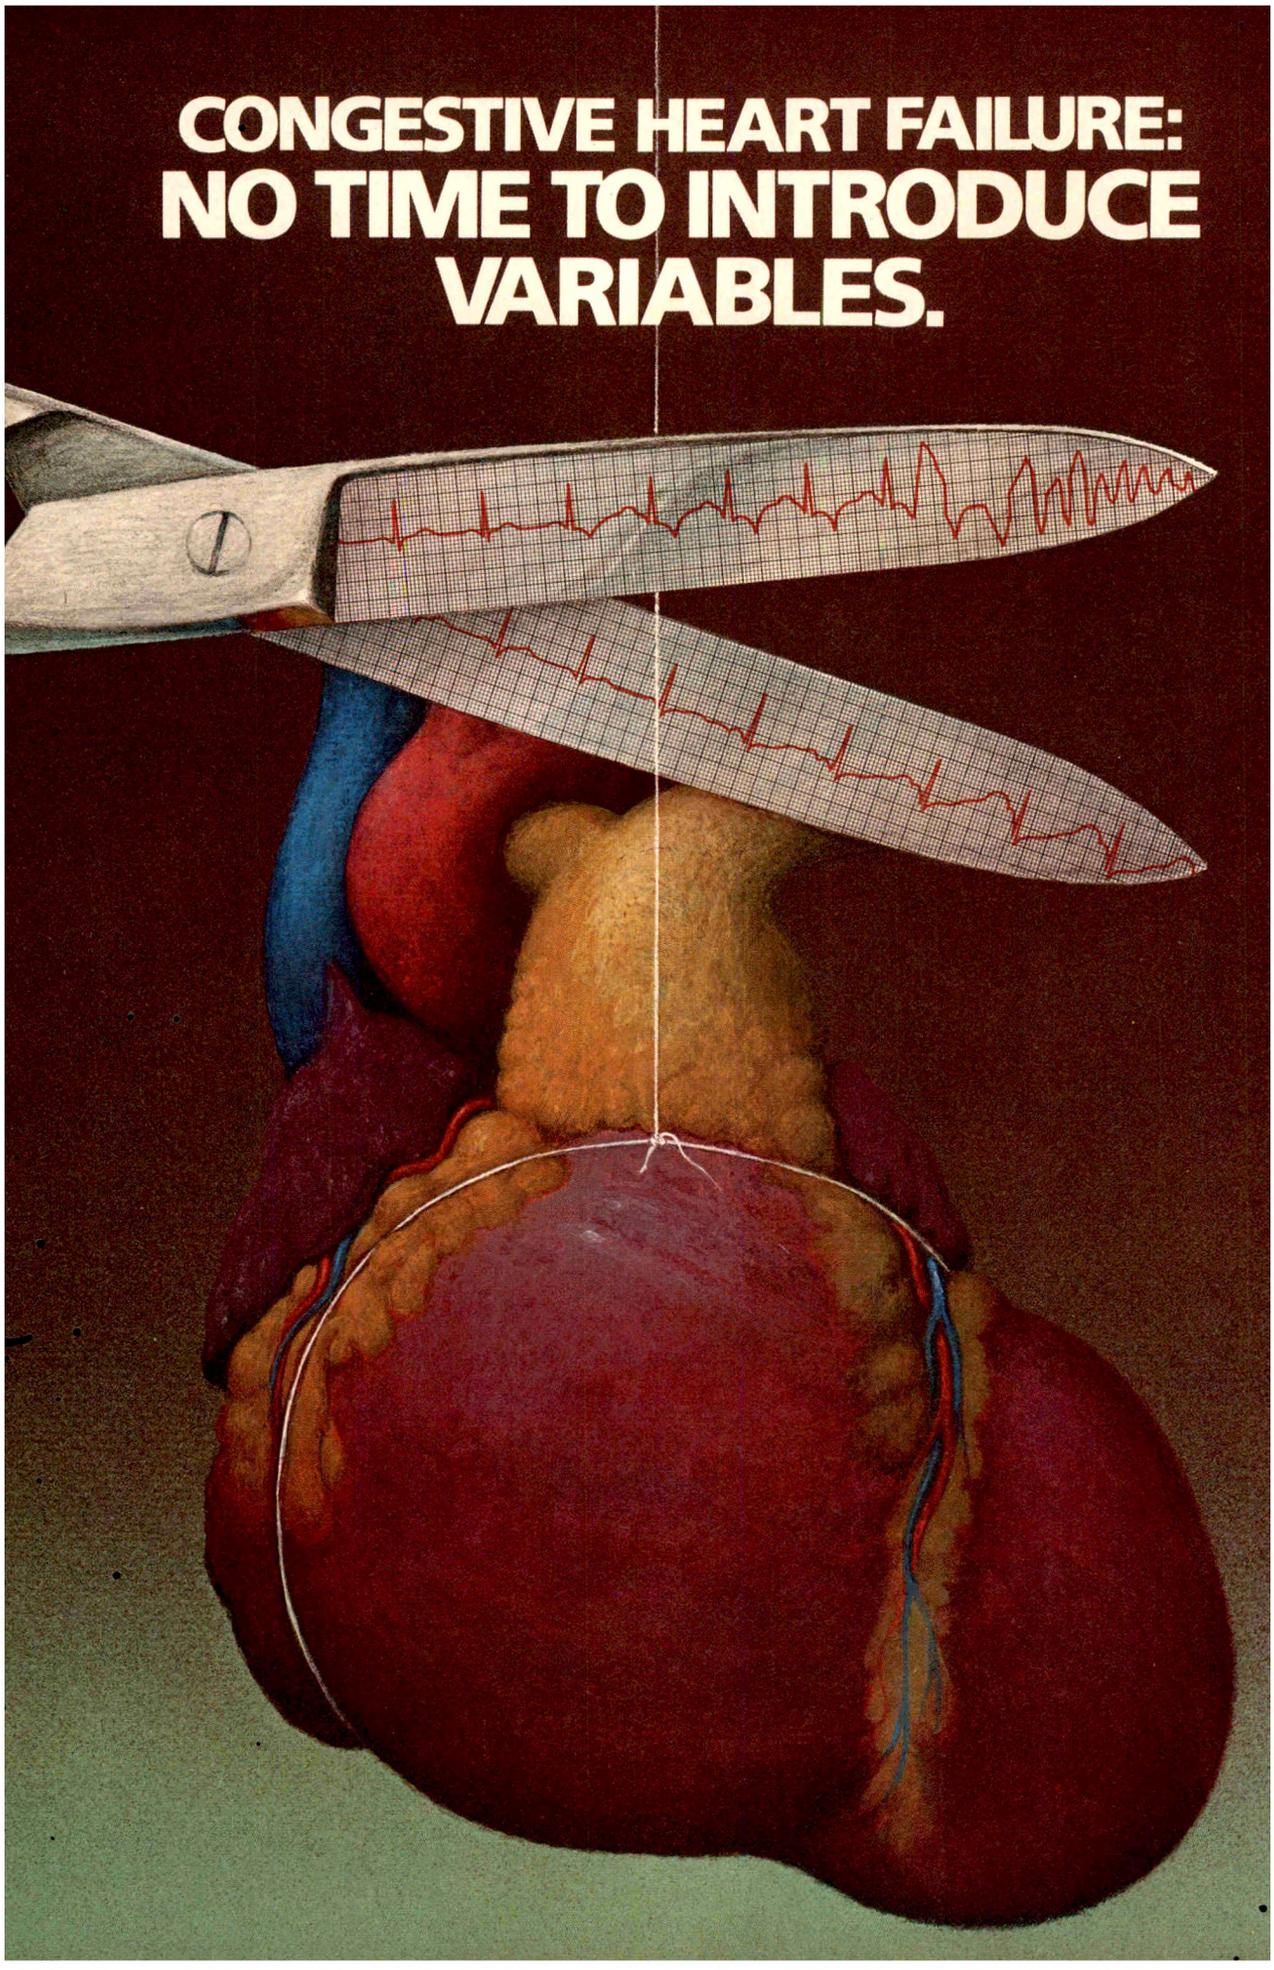
CONGESTIVE HEART FAILURE: NO TIME TO INTRODUCE VARIABLES.



If you wouldn't think of changing your brand of digitalis, shouldn't you think twice before switching from LASIX® furosemide to a substitute?

BRAND OF

Both digitalis and diuretics are almost always used in congestive heart failure. But both can cause serious cardiac arrhythmias.[1] Digitalis, because digitalization is one of the most precarious titrations in all of medicine. And diuretics, because diuretic-induced hypokalemia increases the vulnerability to digitalis toxicity.[2] See warnings and precautions in the brief summary of product information on the next page.

In serious congestive heart failure, the diuretic most frequently administered with digitalis is LASIX® brand of furosemide. However, the bioavailability of furosemide may be significantly altered by a change in tablet disintegrants and/or excipients.[3,4,5] And variations in the bioavailability of unlawfully-marketed furosemide tablets have produced unpredictable and serious clinical effects.[6]

Therefore, once the patient is stabilized on digitalis and LASIX®, changes in his cardiac regimen should be minimized.

LASIX®—the diuretic with the best record of success in all degrees of congestive heart failure.

LASIX® is the original brand of furosemide. It is LASIX® that established the standard for furosemide performance. It is LASIX® that is the subject of almost 6,000 published papers. It is LASIX® that has been used successfully in millions of digitalized patients over the past 14 years. And it is LASIX® that has a remarkable quality-control record—almost 8 billion tablets manufactured without a single product recall.

LASIX® tablets are available in a dosage strength to meet almost every patient need—20, 40 and 80 mg.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

IN CONGESTIVE HEART FAILURE.

LASIX®

FUROSEMIDE

ONE LESS VARIABLE IN THE DIGITALIZED PATIENT

Lasix® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide). Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Because animal reproductive studies have shown that furosemide may cause fetal abnormalities, the drug is contraindicated in women of childbearing potential. Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use.

It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion; this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exe
its role in Diagnosis, Treatment, and Prevention c
disease.

The scope of EXERCISE IN CARDIOVASCULAR AND DISEASE is so broad that it goes from something a detailed study of the heart muscle itself to the latest a cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training i physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asy population

The editors have brought together a distinguishec specialists—all of whom have made major contributi field. Included are outstanding scientists, clinicians physiologists, and physical educators.

For you who have any interest—professional or per exercise and the heart, we urge you to *look* at EXERCISE IN CARDIOVASCULAR HEALTH AND That's right! You're invited to *look* it over before b

Send for your copy of Exercise in Cardiovascular H Disease today. *Then use it for 30 days without risk.*

KAON CL-10™
(potassium chloride)
10 mEq Controlled Release Tablets

Easy-to-remember b.i.d. dosage

Just one KAON CL™-10 wax-matrix tablet b.i.d. supplies 20 mEq KCl. Two tablets b.i.d. supply 40 mEq KCl.

Easy to comply

B.i.d. instead of conventional t.i.d. dosage makes it easier for your patients to follow your instructions...increases likelihood of full compliance.

Easy to take, easy to carry

KAON CL-10 tablets have no taste or aftertaste...can be easily carried anywhere.

Easy dosage adjustment

Dosage may be individually adjusted, based on logical, easy-to-determine multiples of 10.

Easy on the purse

KAON CL-10 tablets offer your patients greater economy because fewer tablets deliver the same amount of potassium at a lower cost.

Easy on the GI tract

Special wax-matrix delivery system permits gradual release of KCl over several hours to minimize high localized concentrations in the GI tract, thus minimizing the chance of GI irritation. The frequency of small bowel lesions with wax-matrix tablets is less than one per 100,000 patient years.

for patients who can't or won't take liquid supplements

Brief Summary

Description: Kaon Cl™-10 mEq is a sugar coated (not enteric-coated) tablet containing 1,750 mg potassium chloride (equivalent to 10 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control mild cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon Cl™-10 mEq (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) tha with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) case associated with wax-matrix tablets have been reported both in foreign countries and in th United States. In addition, perhaps because the wax-matrix preparations are not enteric coated and release potassium in the stomach, there have been reports of upper gastroir testinal bleeding associated with these products. The total number of gastrointestina lesions remains less than one per 100,000 patient years. Kaon Cl-10 mEq should be dis continued immediately and the possibility of bowel obstruction or perforation considered severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated wit an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassiur acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstratin hypokalemia in a patient with a clinical history suggesting some cause for potassium deple tion. In interpreting the serum potassium level, the physician should bear in mind that acut alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassiur while acute acidosis per se can increase the serum potassium concentration into the norma range even in the presence of a reduced total body potassium. The treatment of potassiur depletion, particularly in the presence of cardiac disease, renal disease, or acidosis require careful attention to acid-base balance and appropriate monitoring of serum electrolytes, th electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nau sea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation c the gastrointestinal tract and are best managed by diluting the preparation further, taking th dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings an Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretor mechanisms for potassium rarely causes serious hyperkalemia. However, if excretor mechanisms are impaired or if potassium is administered too rapidly intravenously, poten tially fatal hyperkalemia can result (see Contraindications and Warnings). It is important t recognize that hyperkalemia is usually asymptomatic and may be manifested only by a increased serum potassium concentration and characteristic electrocardiographic change (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the Q interval). Late manifestations include muscle-paralysis and cardiovascular collapse fron cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-2 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized o digitalis, too rapid a lowering of the serum potassium concentration can produce digitali toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100 and 500; Stat-Pak® (Unit-Dose) box of 100.

a "clean break" from the past in angina pectoris*

One press of a finger solves two problems

1. for the physician: more precise dosage titration
2. for the patient: easier compliance with your dosage adjustments

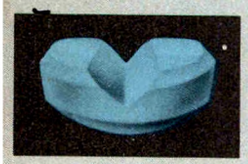
ISORDIL® TITRADOSE®

(ISOSORBIDE DINITRATE) (E.Z. SPLIT®†) Oral Tablets: 5 mg, 10 mg, 20 mg, and 30 mg

NOW...for greater convenience and compliance in the higher spectrum of the recommended dosage range

30 mg ISORDIL® TITRADOSE®

(ISOSORBIDE DINITRATE) Oral Tablets



Tablet shown larger than actual size.

© 1979 Ives Laboratories Inc.

***Indications:** Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:
"Possibly" effective: When taken by the oral route, Isordil is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded as useful in the prophylactic treatment of angina pectoris.
Final classification of the less-than-effective indications requires further investigation.

Contraindication: Idiosyncrasy to this drug.

Warnings: Data supporting the use of nitrites and nitrates during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

Precautions: Tolerance to this drug and cross-tolerance to other nitrites and nitrates may occur.

Adverse Reactions: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents. An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

Dosage and Administration: Isordil (Isosorbide Dinitrate) Oral Titradose Tablets are administered orally. The dosage range is 5 mg to 30 mg q.i.d., with the usual dosage being 10 mg to 20 mg q.i.d.

Consult direction circular before prescribing.

Improved Exercise Performance in Persons With Stable Angina Pectoris Receiving Diltiazem

KENNETH F. HOSSACK, MD*
ROBERT A. BRUCE, MD, FACC

with the technical assistance of
SHIRLEY TRIMBLE
FUSAKO KUSUMI

Seattle, Washington

The effects of diltiazem, a calcium antagonist drug, were compared with those of placebo on exercise performance during a series of symptom-limited upright exercise tests. Ten patients with chronic stable angina were studied over a period of 7 weeks. The drug was administered in a random double-blind fashion and was evaluated at increasing dose levels of 120, 180 and 240 mg/day. Diltiazem was effective in increasing the total duration of exercise ($p < 0.001$) and the time to the first onset of angina ($p < 0.02$) and to the first appearance of 1 mm of S-T depression ($p < 0.02$). These effects were most marked at the highest dose level of diltiazem. The heart rate was reduced at rest ($p < 0.05$) and during submaximal exercise ($p < 0.001$). There was a reduction in diastolic blood pressure during submaximal exercise ($p < 0.04$) but no change in systolic pressure. Pressure-rate product was significantly reduced at submaximal ($p < 0.001$) but not maximal exercise. The reduction in pressure-rate product is postulated as the mechanism by which diltiazem enhances duration of exercise. There was no reduction in electrocardiographic evidence of myocardial ischemia at peak exercise by either clinical observation or computer analysis of spatial electrocardiographic variables. Five of the six patients who continued to take the drug maintained or improved their exercise performance on follow-up study 8 to 10 months later.

Specific pharmacologic agents[1] are now available that inhibit the influx of calcium ions during cell depolarization of both smooth and cardiac muscle. The partial inhibition of calcium passage into smooth muscle cells causes them to contract less vigorously. The theoretic possibility then arises that such drugs may be efficacious in the treatment of angina pectoris. Mechanisms for their effectiveness include dilatation of coronary arteries, with a resulting increase in coronary blood flow and reduced blood pressure, causing decreased myocardial oxygen demand during exertion. If calcium antagonists prove effective in the treatment of angina pectoris, they may be of special benefit to persons who also manifest varying degrees of airway obstruction and are unable to tolerate beta receptor blocking agents. Verapamil[2–4] and nifedipine,[5,6] two other "calcium antagonists," are reported to improve the symptomatic status of persons with angina pectoris. Diltiazem (d-3-acetoxy-cis-2,3-dihydro-5-[2-(diphenyl amino)-ethyl]-2(p-methoxyphenyl) 1,5-benzothiazepine-4(5H)-one hydrochloride) is another calcium antagonist; several studies[7–10] document the effectiveness of this drug in controlling symptoms of coronary arterial spasm.

There are few reports concerning the effectiveness of diltiazem in the treatment of angina pectoris caused by fixed stenoses in coronary arteries. This study describes the results of a double-blind study of diltiazem versus placebo in patients with angina pectoris whose responses to symptom-limited exercise testing were used to assess the effects of the drug.

Methods

Study patients: Nine men and one woman were studied. The requirements for inclusion in the study were typical angina pectoris occurring 5 to 15 times/week, angina during exercise testing and 1 mm or more of horizontal or downsloping S-T depression during exercise testing. No patient was considered clinically to have coronary arterial spasm because none had chest pain at rest or nocturnal angina. Testing of response to ergonovine maleate or to sublingual nitroglycerin was not performed at cardiac catheterization. Patients with unstable angina, recent myocardial infarction (within 6 months) or significant noncardiac diseases were excluded. The physical characteristics, arteriographic findings and medical therapy of the patients before entry into the study are shown in Table I. Five patients were regular participants in a supervised exercise program. Each patient signed an informed consent form approved by the Human Subjects Committee at the University of Washington. None received monetary inducements to participate in the study. During the study, no patient changed his dietary pattern or lost weight. Four patients who smoked continued to do so in the same amount throughout the study. None undertook additional exercise during the study.

Exercise testing: Exercise tests were carried out using a treadmill. Speed and elevation were increased every 3 minutes. The initial speed was 1.7 miles/hour at a 5 percent gradient (stage 1/2) and, when that stage was completed, the test continued using the conventional stages of the Bruce protocol.[11] Subjects performed the test at approximately the same time of day each week and smoking was not permitted for 3 hours before testing. Subjects exercised to symptom-limited end points each time and neither S-T depression nor target heart rate was used as an indication for stopping the test. Heart rate and blood pressure were recorded with the patient seated at rest and then during each stage of the exercise test. The time in seconds from the start of testing to the first awareness of angina was recorded and the total duration of exercise noted. During exercise, the electrocardiogram was monitored using a modified V_5 lead (right scapula, V_5 position). The time from the start of exercise to 1 mm of horizontal or downsloping S-T depression was noted. Frank XYZ lead system signals were recorded on magnetic tape for subsequent computer analysis as previously described.[12]

Drug protocol: Diltiazem was supplied in 30 mg tablets and placebo tablets of identical appearance were also provided. Patients taking beta receptor blocking agents were withdrawn from therapy by incremental reductions in the dosage over a 4 day period. During the 1st week of the study, all patients received placebo, one tablet four times daily. After the 1st week, patients received either placebo or diltiazem in a double-blind random fashion. Three dose levels of diltiazem (120, 180 and 240 mg/day) were evaluated. The number of tablets/day was increased at 2 week intervals. Diltiazem was given in four divided doses during the 1st and final 2 week periods and in three divided doses for the mid 2 week period. Drug compliance was assessed by tablet count in returned bottles. During the study, patients used sublingual nitroglycerin but all other cardioactive drugs were discontinued. Use of nitroglycerin was not permitted immediately before exercise testing.

Patient evaluation: Before entry into the study, the patients performed an exercise test while receiving the medications listed in Table I. Exercise tests were repeated at weekly intervals so that each patient performed a total of eight exercise tests. A urinalysis, hematologic screen and biochemical profile were performed before the 1st week of placebo therapy and then at the end of the 4th and 7th weeks of the study. Each week, patients were questioned regarding possible adverse effects from the tablets.

Statistical analysis: The test results from this double-blind study were analyzed using an analysis of variance (ANOVA) routine from the statistical computing package, SPSS. This routine is capable of handling the repeated measurements made on each patient (for placebo and drug). Because the study was designed to compare diltiazem with placebo and because the patients were taking a variety of medications before the study, the results of the exercise test performed before the study were not included for statistical analysis but are shown for comparison. Comparisons between diltiazem and placebo at the three dose levels were also made using Student's paired t test.

Results

Duration of exercise: The mean and standard error of the mean of exercise duration for the tests are shown in Figure 1. Analysis of variance showed a significant increase in exercise duration while subjects were receiving diltiazem (F 5.1, $p < 0.001$). The difference in

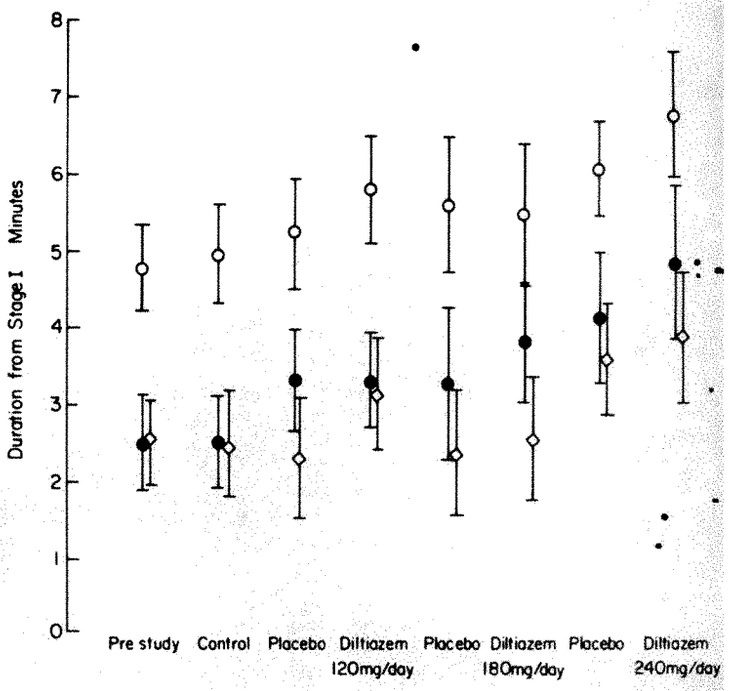

FIGURE 1. The duration in minutes from the beginning of stage I of the Bruce treadmill exercise protocol to the termination of exercise (**open circles**), from the start of stage I to the first onset of angina (**closed circles**) and from the start of stage I to the presence of 1 mm of horizontal or downsloping S-T depression (**open diamonds**) is indicated for each week of the study. Mean values ± standard error of the mean are shown. The prestudy value is shown but not included in the statistical analysis. Analysis of variance revealed a significant increase in the duration of exercise ($p < 0.001$), the time to onset of angina ($p < 0.02$) and the time to 1 mm of S-T depression ($p < 0.02$).

duration at the dose level of 240 mg/day of diltiazem was significant ($p < 0.01$) when compared with that in the corresponding week with placebo. When duration with 120 mg/day of diltiazem was compared with that in the corresponding week with placebo, the p value was not quite significant ($p = 0.056$). Surprisingly, there was no difference in duration at the level of 180 mg/day, and the possibility of subtherapeutic levels of diltiazem due to a prolonged interval between the last dose of the drug and exercise testing was considered. The mean interval from the last dose of diltiazem to exercise testing was 3.6 ± 1.7, 3.3 ± 1.3 and 3.3 ± 1.2 hours for the 120, 180 and 240 mg/day dose levels, respectively. However, three patients whose exercise duration was poorer at the 180 mg dose level had taken the drug at least 4 1/2 hours before testing. A prior study[13] reported that the maximal hemodynamic effect of diltiazem was observed 2 to 3 hours after administration of a single oral dose. Thus it is possible that the failure to observe a difference at the 180 mg/day dose level represents inadequate blood levels at the time of testing in some persons.

Time to first onset of angina: The mean and standard error of the mean of the interval from start of exercise to the first reported awareness of angina are shown in Figure 1. Analysis of variance showed a significant increase in the time to onset of angina while subjects were receiving diltiazem ($F 2.7$, $p < 0.02$). In general, the increase in exercise duration was accompanied by a corresponding increase in the time to first onset of angina. This was true for tests performed during placebo and diltiazem therapy. Table II shows the frequency of exercise-induced angina and exercise limiting angina. Although the frequency of angina decreased slightly while the patients were taking diltiazem, the differences were not significant.

Cardiovascular effects: The observed cardiovascular variables at rest and during exertion are presented in Table III. Overall, the heart rate at rest was reduced with diltiazem ($F 2.3$, $p < 0.05$). Paired t testing showed that the reduction of heart rate at rest at the 180 mg/day dose level was significant ($p < 0.05$). The reduction at 240 mg/day did not reach statistical significance when

* F value obtained from analysis of variance of values obtained while patients were receiving placebo and diltiazem. †,‡ Probability results of paired *t* test comparing results of diltiazem exercise test with corresponding placebo exercise test: † $p < 0.05$; ‡ $p < 0.005$.
p = probability.

compared with the corresponding placebo period although the mean difference was greater than for the 180 mg/day period. The most significant reduction in heart rate (F 7.9, $p < 0.001$) occurred during submaximal exercise. There was a definite increase in the magnitude of reduction with increasing dosage of diltiazem. At maximal exercise, there was no significant change in maximal heart rate although paired *t* testing showed that the mean value for the 180 mg/day period was significantly lower ($p < 0.05$) than the value for the corresponding placebo period. The reason for this finding is not clear and may indicate patient variability or possible failure of several persons to perform maximal exertion.

There were no significant reductions in systolic blood pressure at rest or during exercise. Diastolic blood pressure was significantly reduced at submaximal and maximal exercise. These reductions were most marked when diltiazem was given in a dosage of 240 mg/day.

Pressure-rate product was not significantly changed at rest. There was a highly significant (F 4.0, $p < 0.001$) reduction in submaximal pressure-rate product associated with diltiazem. At maximal exercise pressure-rate product was not significantly reduced.

Electrocardiographic effects: Table IV presents the effects of diltiazem on the electrocardiographic evidence of myocardial ischemia. There was no significant reduction in either the visual reading of S-T depression or the computer measured indexes of myocardial ischemia. Figure 1 shows the time from the commencement of exercise until the appearance of 1 mm of horizontal or downsloping S-T depression. Diltiazem delayed the onset of this electrocardiographic evidence of myocardial ischemia ($p < 0.02$).

Adverse effects: No significant changes in the urinalysis, hematologic or biochemical profiles were observed. One patient reported headaches on two occasions, once while taking diltiazem and once while taking placebo. An additional patient not reported on in Table I who had angina and an occluded right coronary artery

withdrew from the study during the 2nd week because of depression. He was receiving placebo.

Follow-up: At the end of the study all patients were given an opportunity to participate in a long-term study. Six of the patients agreed to do so and they have now been followed up for 8 to 10 months. The remaining four declined; two (Cases 2 and 4) recommenced propranolol therapy and the other two (Cases 6 and 7) are taking long-acting nitrates. Of the six who entered the long-term study, one (Case 3) underwent successful aorto-coronary vein bypass grafting after 4 months; the other five continue to take diltiazem (240 or 360 mg/day). The results of exercise testing, including measurement of maximal oxygen uptake, are shown in Table V. Included in this table are control values for comparison. The five patients who are currently taking the drug showed significant improvement with a measured increase in maximal oxygen uptake as well as enhanced duration of exercise. Changes in heart rate and pressure-rate product with long-term usage of diltiazem are consistent with the findings in the short-term study.

Discussion

Beneficial effects of diltiazem in angina pectoris: The results of this study are encouraging because they indicate that diltiazem, in a dosage of 240 mg/day, was associated with an increased duration of exercise, prolonged the time to onset of angina and eliminated angina as the symptom for limiting exercise in some cases. When the duration of exercise during the treatment period of 240 mg/day of diltiazem was compared with the exercise test performed immediately before the study, all patients showed an increase ($p < 0.005$) and nine experienced an increase in duration to the onset of angina ($p < 0.05$).

The heart rate and blood pressure responses to exercise observed in this study provide some insight into the possible mechanism by which diltiazem and possibly calcium antagonists in general exert a beneficial effect. It appears that heart rate is reduced at rest and at submaximal exertion, but there was no significant change in maximal heart rate during exercise.

Comparisons with nifedipine and verapamil: Moskowitz et al.[6] found that nifedipine, another calcium antagonist, did not alter heart rate at rest, but Eklund and Oro[5] reported a significant increase in heart rate with nifedipine during upright bicycle exercise. In a report[3] of the effects of verapamil, maximal heart rate was reduced but two other studies[2,4] recorded no change in heart rate. The mechanisms for the heart rate responses are not clear but a possible explanation for the increased heart rate response with nifedipine is a reflex tachycardia associated with afterload reduction because systolic blood pressure was significantly reduced at rest and at submaximal and maximal exercise. In contrast, verapamil was reported to cause no change in heart rate despite a reduction in systolic blood pressure in one study,[4] and in another[3] heart rate was reduced without a change in systolic pressure. Similarly, the results of our study with diltiazem show reductions in heart rate without changes in systolic blood pressure at submaximal exertion. Kinoshita et al.,[14] using a single oral dose of 60 mg of diltiazem, found reductions in heart rate at rest and systolic blood pressure but no change in values during supine bicycle exercise. It is possible that verapamil and diltiazem may depress sinoatrial nodal automaticity as a result of calcium blockade to account for the heart rate responses. Verapamil prolongs atrioventricular conduction whereas nifedipine does not have such an effect in human beings.[15] It is apparent there are electrophysiologic differences among the various calcium antagonists and there may well be varying he-

modynamic differences. A consistent finding confirmed by this study and reported for nifedipine,[6] verapamil[2,4] and diltiazem[14] was the decrease in diastolic pressure suggesting that there was a decrease in peripheral resistance.

Effect on electrocardiographic evidence of ischemia: Our study failed to show any reduction in electrocardiographic evidence of myocardial ischemia at peak exercise. Too few patients experienced a significant amount of S-T depression during stage 1/2 and stage 1 to evaluate the effect of diltiazem on myocardial ischemia at submaximal exercise levels. However, the time to onset of 1 mm of S-T depression was significantly prolonged with diltiazem, suggesting that diltiazem does reduce electrocardiographic evidence of ischemia. Results of studies with verapamil[2,3] and nifedipine[6] suggested that these drugs decrease the magnitude of electrocardiographic evidence of myocardial ischemia during exercise. The reduction in pressure-rate product is indirect evidence of decreased myocardial oxygen demand.[16]

Dosage schedule: The dosage of diltiazem chosen for this study was based on Japanese data,[7–10,14] which showed impressive symptomatic and hemodynamic changes with small doses (total 90 mg/day). In prescribing diltiazem, an initial dosage of 240 mg/day would appear to be appropriate and further studies evaluating the effect of 360 mg/day are in progress. Because more consistent findings were found with a schedule of four rather than three times daily, the former is preferred.

Possible limitations of study: This study design imposes some limitations on the interpretations of the results. There was a nonspecific increase in exercise duration as the study progressed (Fig. 1). This was partly due to the increasing familiarity of the patients with the equipment and exercise protocol; however, all subjects had prior experience of treadmill testing on several occasions. It was unlikely that a training effect occurred and certainly there was no hemodynamic changes to support a training effect (that is, no significant change in submaximal pressure-rate product for the weeks of placebo therapy). When the control values were compared with those of the last week of placebo therapy and the last week of diltiazem therapy, the change was greater with diltiazem ($p < 0.005$) than with placebo ($p < 0.005$). Similarly, the time to onset of angina increased more with diltiazem ($p < 0.02$) than with placebo ($p < 0.05$). However, the statistical analysis using analysis of variance gives a more meaningful assessment of the significance of changes associated with diltiazem.

The long-term follow-up data on the six patients who continued to receive diltiazem were consistent with a beneficial effect of the drug. The small number of patients studied imposed limitations on the study and may have been responsible for some of the variation seen in the maximal heart rate at the dosage of 180 mg/day of diltiazem. A study comparing the effects of diltiazem with standardized conventional therapy in persons with angina over a long period of time would provide an additional assessment of the efficacy of diltiazem. Another aspect that should be evaluated in such a study is the possible difference between calcium antagonists and beta receptor blocking agents with regard to causing fatigue. In our study, six of the eight patients who were taking beta blocking agents before testing noted a loss of fatigue when these agents were discontinued during the study. Several also noted that their ability to perform cognitive duties was greater during the study period than during periods of propranolol usage.

Clinical implications: Diltiazem is an effective drug in the symptomatic treatment of exercise-induced angina pectoris. Undoubtedly, the relative contributions of coronary arterial spasm and fixed arterial obstructions to the pathophysiology of angina vary among patients. Some in whom spasm is the dominant factor may derive the greatest symptomatic benefit from diltiazem and similar compounds. In this study, no patient had clinical evidence of coronary spasm and all manifested improved exercise performance over the prestudy test results while receiving the highest dosage of diltiazem, thus suggesting that this drug is effective even in the presence of fixed coronary artery disease. In the dosages used and in the short period of time studied, diltiazem had remarkably few adverse effects. Because diltiazem may facilitate the adaptive responses to physical training, compliance and adherence to a training schedule may be enhanced. A recent report indicated that patients taking verapamil after myocardial infarction were able to participate successfully in an exercise program.[17] In contrast, serious doubts have been raised concerning the ability of patients receiving propranolol to obtain a significant training effect.[18,19] The occasional clinical problem of a patient with reversible airway obstruction and angina may be an additional indication for treatment with diltiazem.

Left ventricular anterior wall motion and distribution of coronary perfusion were assessed by contrast cineangiography and the dual isotope-labeled intracoronary microsphere technique before and after intravenous or intracoronary administration of nitroglycerin in 30 patients with significant left anterior descending coronary artery disease and resting anterior wall asynergy. Perfusion was measured in 11 additional control patients before and after administration of saline solution. Reversible asynergy was observed in 6 (43 percent) of 14 patients after systemic (intravenous) nitroglycerin and in 7 (44 percent) of 16 patients after intracoronary nitroglycerin. Significant reductions of blood pressure and improved wall motion were noted in both groups receiving nitroglycerin, suggesting afterload reduction as the common mechanism. There was also a small increase in end-diastolic volume index in patients with reversible asynergy after intracoronary administration of nitroglycerin, but no significant trends in preload change after intravenous administration. Ejection fraction increased significantly in patients with reversible asynergy after both intravenous and intracoronary nitroglycerin. Both intravenous and intracoronary nitroglycerin resulted in significant increases and decreases in distribution of coronary perfusion to the anterior wall. However, these changes were randomly distributed and improved perfusion did not consistently occur with improved wall motion.

In conclusion, both intravenous and intracoronary nitroglycerin may reverse wall motion asynergy and produce both favorable and unfavorable changes in perfusion in patients with coronary disease. The common mechanism in improving wall motion with either intravenous or intracoronary nitroglycerin was afterload reduction, suggesting that the systemic effects of nitroglycerin are the most important in reversing asynergy.

Nitroglycerin has been used at the time of left ventricular angiography to improve wall motion of impaired segments of the left ventricle in patients with coronary artery disease.[1–4] Nitroglycerin could have a beneficial effect on impaired wall motion through various mechanisms, including its systemic effect on preload and afterload,[5–8] redistribution of coronary flow to ischemic segments[9,10] or possibly a direct myocardial effect.[11] Previous clinical studies have produced conflicting results, particularly in respect to alterations in coronary flow and its distribution[9,10,12,13] and have not discriminated among the relative contributions of these effects. To determine the mechanism of action of nitroglycerin on wall motion, we studied the effects of both systemic and intracoronary nitroglycerin on wall motion and distribution of coronary flow in patients with coronary disease.

Methods

Study patients: Forty-one patients undergoing cardiac catheterization with selective coronary arteriography were studied. There were 37 men and 4 women, with a mean age of 49.6 years (range 32 to 64). Thirty patients had triple vessel coronary artery disease, six had double vessel disease, three had single vessel disease and two had normal coronary arteries. All patients receiving nitroglycerin had 75 percent or greater stenosis of the diameter of the left anterior descending artery and resting anterior wall motion abnormalities. In all but one patient the stenosis of the left anterior descending artery was at or proximal to the first septal perforator. Of the 11 control patients, 2 had normal coronary arteries and 9 had disease of the left anterior coronary descending artery. All patients except the two in the control group with normal coronary arteries had stable angina pectoris of grade II or III severity (New York Heart Association classification).[14] None had congestive heart failure and all had sinus rhythm. Thirteen of the study group receiving nitroglycerin had Q waves or no "R wave progression" in the precordial leads diagnostic of a previous anterior myocardial infarction. Eight patients had angiographically visualized collateral vessels to the left anterior descending coronary artery (see Results). In all patients administration of nitroglycerin and long-acting nitrates had been discontinued 24 hours or more before study. The dosage of propranolol was reduced to 80 mg/day or less before catheterization. In two patients receiving digoxin administration of the drug had been discontinued for at least 24 hours before the study. All patients gave signed, informed consent.

Protocol: After the patients were premedicated with 50 to 75 mg of Demerol® and 25 mg of Phenergan® intramuscularly, two catheters were inserted, one in each groin, by the percutaneous femoral technique. A pigtail catheter was placed in the left ventricle and a left Judkins catheter was placed just above the left coronary ostium. Baseline aortic pressures and heart rate were recorded. The left Judkins catheter was then placed in the ostium of the left coronary artery and its position verified by injection of a minimal amount (less than 0.5 cc) of Renografin-76®. Macroaggregated human serum albumin (0.5 to 0.8 ml.) labeled with 2 millicuries (mCi) of technetium-99m was selectively injected into the left coronary artery. Sixteen patients then received 0.06 mg of nitroglycerin into the left coronary artery and 14 received 0.4 mg of nitroglycerin intravenously. Eleven patients who served as a control group received an equal volume of saline solution. Macroaggregated human serum albumin (0.5 to 1.0 ml) labeled with 100 mCi. of iodine-131 was selectively injected into the left coronary artery when peak changes in pressure and heart rate were obtained in the patients receiving intravenous nitroglycerin or within 15 seconds in patients receiving intracoronary nitroglycerin and those in the control group.

A waiting period of 20 minutes was then allowed for dissipation of the effects of the previous administration of nitroglycerin with return of aortic pressure and heart rate to control levels. A left ventricular angiogram was then performed with 40 to 45 cc of Renografin-76 at an injection rate of 12 to 14 ml/s with the patient in the 30° right anterior oblique position. After a second rest period, nitroglycerin was again given by the same route and in the same dose as previously and a postnitroglycerin angiogram was performed using the same quantity and injection rate of dye as before. This angiogram was performed at precisely the same time after administration of nitroglycerin as described for injection of the second labeled macroaggregate. Selective coronary arteriograms were then performed by the Judkins technique in multiple views. There were no complications associated with the procedure.

Myocardial imaging techniques: After completion of the cardiac catheterization, myocardial imaging was performed on a Toshiba large field of view gamma camera with a dual nuclide adaptor using a high energy parallel hole collimator. Iodine-131 was peaked at 360 KeV with a 20 percent window and technetium-99m was peaked at 140 KeV with a 20 percent window. Patients were imaged in the 45° left anterior oblique position in order to separate accurately left anterior descending and circumflex arterial perfusion territory. Data were stored in a PDP 11/40 computer for subsequent analysis. Counts within irregular areas of interest corresponding to the distribution of perfusion of the left anterior descending artery were normalized by expressing them as a fraction of counts in the total myocardium. The ratio of counts before and after administration of nitroglycerin was calculated for that perfusion territory. The significance of changes in perfusion was determined by comparing count ratios before and after nitroglycerin in the study group with those in the control group using the unpaired Student's t test. Changes in the left anterior descending arterial distribution of perfusion after nitroglycerin were then compared with changes in anterior wall motion assessed angiographically.

Analysis of cineangiograms: End-diastolic and end-systolic silhouettes were drawn from contrast cineangiograms with a calibration mark included. These silhouettes were taken within the first 3 beats of the angiogram and were not preceded by a ventricular premature complex. Volumes were calculated using a computer-assisted modification of Simpson's rule[15] and ejection fraction was derived. The long axis from the mid aortic plane to the apex was quadrisected, and three perpendicular chords drawn to the anterior wall for the end-diastolic and end-systolic frames.[16] The percent of chordal shortening for the angiograms obtained before and after nitroglycerin was calculated and the average change of the three anterior wall chords used. The angiographic data obtained before and after nitroglycerin were compared using the paired Student's t test.

Results

Angiographic Analysis of Wall Motion

Analysis of anterior wall motion in the contrast angiograms showed the following responses to nitroglycerin. After intravenous nitroglycerin 6 of 14 patients demonstrated a greater than 5 percent increase in anterior wall percent chord shortening (Fig. 1A); the remaining 8 showed either no change or a decrease. After intracoronary nitroglycerin 7 of 16 patients showed a greater than 5 percent increase in anterior wall percent chord shortening; and 9 showed no change or a decrease (Fig. 1B). Intravenous nitroglycerin significantly reduced systolic blood pressure in patients with improved and unimproved anterior wall motion (Fig. 2). The mean (± standard error of the mean) decrease in systolic blood pressure was 31 ± 6 mm Hg for those with improved anterior wall motion and 19 ± 4 mm Hg for those with unimproved wall motion. There was no significant difference between these two mean values. Intracoronary nitroglycerin produced a much smaller but significant (7 ± 3 mm Hg) mean decrease in those with improved wall motion, and no significant trend in those with unimproved anterior wall motion. No significant trends were seen in changes in mean heart rate with intravenous nitroglycerin. However, there was a small but significant increase in mean heart rate from 58 ± 3 to

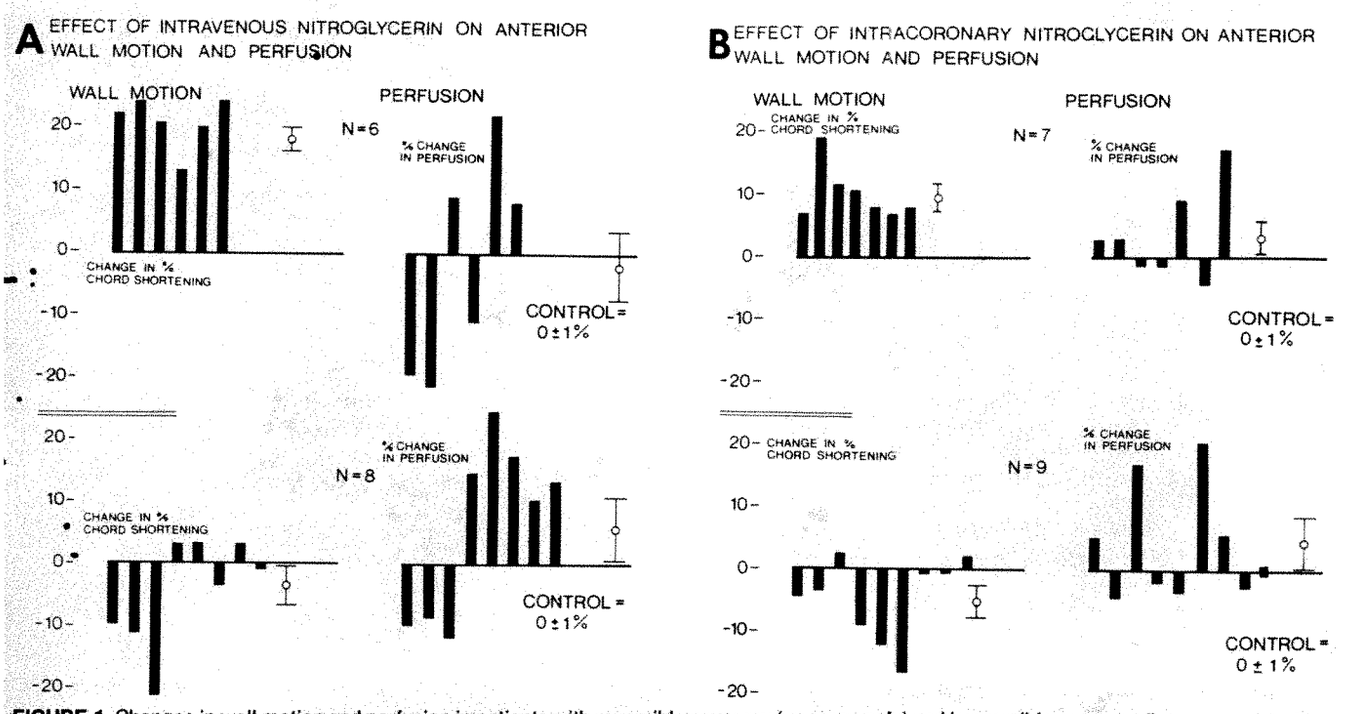

FIGURE 1. Changes in wall motion and perfusion in patients with reversible asynergy (**upper panels**) and irreversible asynergy (**lower panels**) after intravenous (A) and intracoronary (B) administration of nitroglycerin.

62 ± 2 beats/min with intracoronary nitroglycerin in those with improved anterior wall motion.

End-diastolic volume index (Fig. 3) significantly increased by a small amount in the group with improved anterior wall motion after intracoronary nitroglycerin, but no significant changes in this index occurred in the other groups. Global ventricular function as measured by ejection fraction (Fig. 4) improved significantly in those patients with improved wall motion after either intravenous or intracoronary nitroglycerin, but did not improve in patients with irreversible asynergy of the anterior wall.

Three of six patients with improved wall motion after intravenous nitroglycerin and three of the eight with unimproved wall motion had anterior Q waves in the electrocardiogram. In the group given intracoronary nitroglycerin one of the seven patients with improved wall motion and six of the remaining nine patients with unimproved wall motion had anterior Q waves.

Analysis of collateral circulation in the group receiving intravenous nitroglycerin revealed six patients with collateral circulation to the left anterior descending coronary artery, including four with improved wall motion and two with unimproved motion. In the group receiving intracoronary nitroglycerin, no patients with improved wall motion and two with unimproved motion had collateral circulation to the left anterior descending artery.

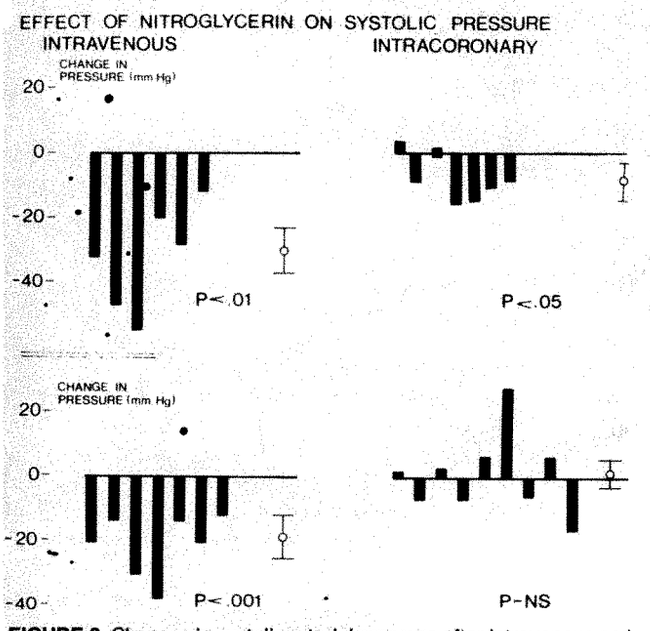

FIGURE 2. Changes in systolic arterial pressure after intravenous and intracoronary administration of nitroglycerin in patients with reversible asynergy (**upper panels**) and irreversible asynergy (**lower panels**).

Coronary Perfusion Analysis

To assess the variability of the dual isotope technique for measuring changes in the distribution of perfusion in a single coronary vessel after an intervention, 11 control patients were studied. The mean change (± standard error of the mean) in distribution of perfusion in the left anterior descending arterial territory measured by the two isotopes after saline solution alone was 0.0 ± 1.0 percent. The significance of changes in distribution of perfusion in patients receiving nitroglycerin

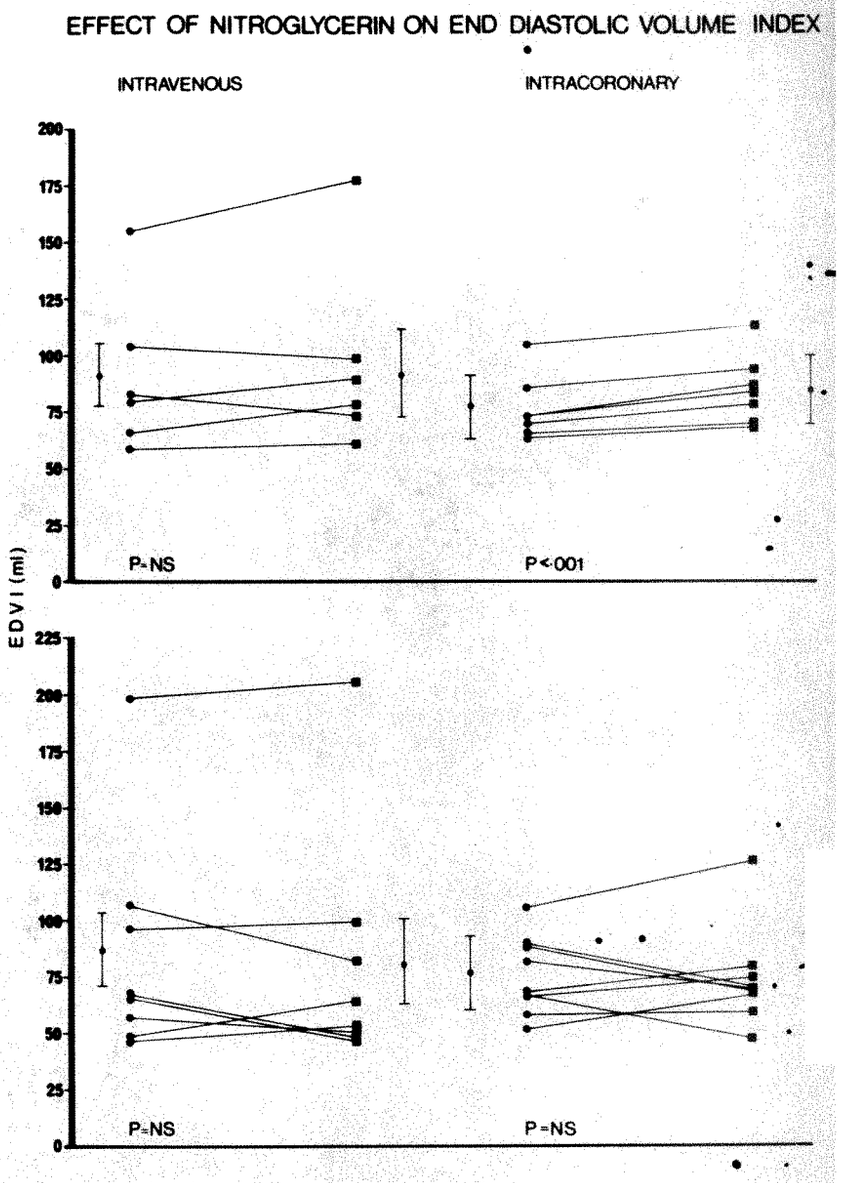

FIGURE 3. Changes in end-diastolic volume index (EDVI) after intravenous and intracoronary administration of nitroglycerin in patients with reversible asynergy (**upper panels**) and irreversible asynergy (**lower panels**).

was determined by comparison with this control value. In patients receiving intravenous nitroglycerin there were significant increases and decreases in distribution of perfusion in the territory of the left anterior descending coronary artery with both improved as well as unimproved wall motion. However, these changes were randomly distributed and did not correlate with wall motion changes (Fig. 1A). Similarly, in the patients receiving intracoronary nitroglycerin there were small but still significant increases and decreases in perfusion, but no correlation with changes in wall motion (Fig. 1B).

In order to determine the possible effect of changes in end-diastolic pressure on perfusion, these pressures were compared before and after intracoronary nitroglycerin in patients with improved perfusion and in those with no change or decreased distribution to the anterior wall. There were no significant differences in end-diastolic pressures before and after intracoronary nitroglycerin for either group (13.7 ± 4.8 versus 15.1 ± 5.8 mm Hg, p = NS, increased perfusion; 15.1 ± 10.1 versus 15.8 ± 9.4 mm Hg, p = NS, no change or decreased perfusion) (mean ± standard deviation).

Discussion

Effects of Nitroglycerin on Wall Motion

Mechanisms of improved ventricular wall motion: Nitroglycerin given at the time of left ventricular angiography has been shown to improve impaired left ventricular segmental wall motion in some patients with coronary artery disease.[1–4] Several mechanisms could contribute to this observed improvement. Nitroglycerin reduces afterload by decreasing systemic pressure which would directly enhance fiber shortening.[7,17] Its effect in reducing both preload and afterload would reduce oxygen requirements of an ischemic segment and could thereby improve its contractility.[5–8] Nitroglycerin could

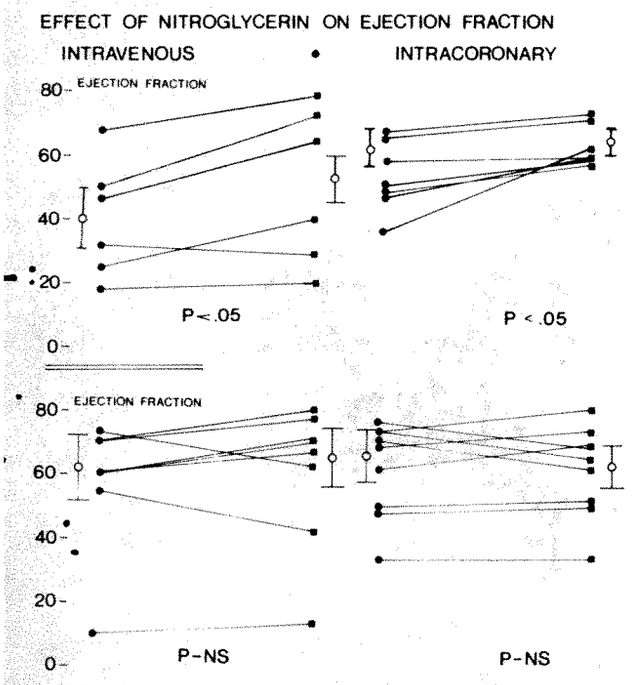

FIGURE 4. Changes in ejection fraction after intravenous and intracoronary administration of nitroglycerin in patients with reversible asynergy (**upper panels**) and irreversible asynergy (**lower panels**).

also induce a redistribution of perfusion to ischemic zones and improve oxygen supply.[9,10] Finally, a direct or indirect inotropic action has been suggested.[11] The operative mechanism was not investigated in these initial studies. Further studies have provided evidence for the link between reversible asynergy and reversible myocardial ischemia. Studies by Banka[18] and Bodenheimer[19] and their co-workers have shown that coronary arterial narrowing may produce resting reversible asynergy in zones of histopathologically normal myocardium. Our results concur with theirs in that the presence of Q waves was associated with unimproved wall motion after intracoronary nitroglycerin, although there was no such trend in the patients given intravenous nitroglycerin. More recent studies with thallium-201 myocardial scintigraphy[20,21] have shown that zones with reversible asynergy are associated with exercise-induced perfusion defects. Both experimental[22] and clinical[23] studies have shown an improvement in asynergy with reperfusion of zones supplied by a narrowed coronary artery.

All of these data suggest that asynergy reversible with nitroglycerin is the result of a favorable alteration of the myocardial supply-demand ratio in ischemic but anatomically normal myocardium. However, these studies have not determined if this reversibility results from a direct effect of nitroglycerin on distribution of flow or a reduction of myocardial oxygen demand or perhaps a combination of both. In our study we compared the effects of intravenous and intracoronary nitroglycerin to distinguish direct coronary from systemic effects. We also assessed the effects of systemic and intracoronary nitroglycerin on distribution of coronary flow to determine if changes in wall motion were related to changes in flow.

Effect on ventricular afterload: Systemic nitroglycerin, as expected, resulted in a decrease in systolic arterial pressure. In 43 percent of these patients anterior wall motion was improved after nitroglycerin (Fig. 1A). This improvement could be secondary to any of the previously mentioned factors, including both the effects of nitroglycerin on afterload and coronary perfusion. In the group receiving intracoronary nitroglycerin 44 percent of patients had improved anterior wall motion associated with a small but significant decrease in systolic pressure. The other 56 percent of patients had no improvement after intracoronary nitroglycerin and no significant change in blood pressure even though several had redistribution of perfusion to the anterior wall. This observation suggests that the improved wall motion could have been secondary, at least in part, to the effect of the nitroglycerin, after passing through the coronary circulation, reaching the systemic vascular bed and reducing blood pressure. These data in both the group receiving intracoronary and that receiving systemic nitroglycerin point to afterload reduction as a common factor improving wall motion.

Effect on preload: The other recognized systemic effect of nitroglycerin is on left ventricular preload. In this study, we observed a variable response, with both decreases and increases in end-diastolic volume. Of interest, there was a small but significant increase in end-diastolic volume in the seven patients with improved wall motion after intracoronary nitroglycerin. This raises the possibility of a small contribution from the Frank-Starling effect, along with the afterload effect, in augmenting wall motion in these patients. This increase in end-diastolic volume in some of the patients is less easily explained than the expected reduction in volume observed by other workers.[5,6] A direct effect of nitroglycerin in reducing left ventricular compliance is possible. Another possibility is a coronary steal effect altering perfusion and contraction outside the territory of the left anterior descending coronary artery, resulting in ventricular dilation. As discussed later, a coronary steal from the right coronary artery to the left anterior descending artery would not be measured by this technique. However, only one of these seven patients with increased end-diastolic volume had collateral vessels and these were from both the left anterior descending and left circumflex arteries to the right coronary artery. The other six patients had no collateral circulation, and thus would be unlikely to have an unmeasured "steal" effect. A more likely explanation would be a reduction in right ventricular volume allowing more complete left ventricular filling.[9,24]

Effects of Nitroglycerin on Coronary Perfusion

We utilized the dual isotopic techinique[25–27] in this study to assess the effect of both systemic and intracoronary nitroglycerin on coronary perfusion. By imaging in the left anterior oblique view after radionuclide injection into the left main coronary artery, the perfusion

territory of the left anterior descending artery, and hence of the anterior wall, can be isolated from circumflex arterial perfusion. To assess the reliability of the method, control patients received technetium-99m or iodine-131–labeled particles in random order before and after intracoronary injection of saline solution. Distribution of perfusion to the left anterior descending territory varied by 1 percent after saline injection. Comparison of the nitroglycerin groups with this control group reveals that both intracoronary and intravenous nitroglycerin resulted in significant changes in distribution of perfusion (Fig. 1). These changes were increased in some patients and decreased in others, indicating that nitroglycerin may have both beneficial and deleterious effects on distribution of flow. Some differences between the effects of intracoronary and intravenous nitroglycerin might have been expected because we compared different patient groups rather than administering nitroglycerin to each patient by the two routes. Nonetheless the effects of nitroglycerin on perfusion were remarkably similar regardless of the route administered.

Direct nitroglycerin effect on coronary circulation: The second important implication of these data is that nitroglycerin has a direct effect on the coronary circulation, as evidenced by the significant changes in the group receiving intracoronary nitroglycerin (Fig. 1B). It is also apparent that there was no consistent trend of increased distribution of flow to those segments with improved wall motion. Although redistribution of flow could have been a factor in improving wall motion in a few patients, it could not explain improvement in most. A limitation of the intracoronary microsphere technique is that changes in distribution of flow are measured but absolute changes in flow are not. Therefore, absolute flow to the anterior wall could increase and improve wall motion without redistribution of flow to that region. In view of the possibility of coronary vasodilatation by nitroglycerin, it would have been desirable to have a measure of absolute coronary flow in these studies. However, the reduction in blood pressure observed in all the patients with improved motion would lower coronary perfusion pressure and make increased coronary flow past significant arterial stenosis less likely. This is consistent with the findings of Bernstein et al.,[8] who demonstrated that intracoronary nitroglycerin in dogs resulted in an early increase in coronary flow that did not persist after arterial pressure decreased. Similarly, Gorlin et al.[12] found that nitroglycerin increases coronary flow in normal subjects but not in patients with coronary artery disease.

Effect of coronary collateral vessels: The other potential source of error in assessing distribution of flow could be the effect of collateral vessels. It is possible that left anterior descending arterial flow could be augmented by collateral flow from the right coronary system without being measured by this technique, since no particles were injected into the right coronary artery. However, only 4 of the 13 patients with reversible asynergy had collateral vessels to the left anterior descending artery, and in fact none of the intracoronary nitroglycerin group. Hence, collateral flow, although possibly playing a role in some, was not a factor in most patients in this study.

Implications: We found that both systemic and intracoronary nitroglycerin improved wall motion of hypokinetic ventricular segments in nearly half of the patients studied. Nitroglycerin resulted in both increases and decreases in distribution of flow to these areas, but these changes in flow did not correlate with changes in wall motion. The one consistent feature in patients with improved wall motion was a decrease in systemic pressure, suggesting that the systemic effect, especially afterload reduction, is the most important effect of nitroglycerin in producing improved wall motion.

Hemodynamic Effects of Molsidomine at Rest and During Submaximal and Maximal Exercise in Patients With Coronary Artery Disease Limited by Exertional Angina Pectoris

JEAN-MARIE R. DETRY, MD
JACQUES MELIN, MD
LUCIEN A. BRASSEUR, MD
JACQUES COSYNS, MD
MICHEL F. ROUSSEAU, MD

Brussels, Belgium

To analyze the mechanisms of action of molsidomine, a new antianginal drug, 10 patients with coronary artery disease and exertional angina pectoris were studied. Hemodynamic measurements were made at rest, during submaximal exercise and during angina-limited exercise before and 1 hour after intravenous administration of 2 mg of molsidomine. When angina pectoris was prevented after the drug was given (6 of 10 patients), the exercise intensity was increased until the recurrence of angina (3 patients) or until exhaustion (3 patients), and hemodynamic data were recorded at this higher exercise capacity.

At rest and during submaximal exercise, molsidomine increased heart rate and decreased cardiac output and mean systemic and pulmonary arterial pressures. The prevention of angina pectoris was attended by lower mean systemic and pulmonary arterial pressures and pressure-rate product; cardiac output and heart rate were unchanged. The greater exercise capacity (+26 percent) after molsidomine was attended by increases in maximal cardiac output (+19 percent) and in arteriovenous oxygen difference (+6 percent); the maximal pressure-rate product was unchanged and systemic vascular resistance was lower. The mechanisms of action of molsidomine are very similar to those of nitrates and imply a decrease in venous and arterial tone. Molsidomine deserves further study in patients with angina or congestive heart failure.

Molsidomine (N-ethoxycarbonyl-3-morpholine-sydnonimine) is a promising new antianginal drug that was introduced in West Germany in 1978. From the available data, the effects of molsidomine are similar to those of nitrates, but they last 5 to 8 hours after oral, sublingual or intravenous administration.[1–8] Previous hemodynamic studies in human beings have shown that at rest molsidomine decreases both the preload and the afterload of the left ventricle;[6–8] at rest the decrease in arterial blood pressure is accompanied by a similar decrease in cardiac output and, consequently, the calculated peripheral resistances appear unchanged.[9–11] These data are in agreement with data from animal studies indicating that the long-lasting hypotensive action of molsidomine is primarily due to a dilation of the capacitance vessels.[12–24]

During exercise, molsidomine induces a moderate decrease in the mean arterial pressure and a marked decrease in the mean pulmonary arterial pressure[6–8] but the effects on cardiac output have not been measured. The goal of this study was to explore the hemodynamic modifications underlying the increase in physical working capacity induced by molsidomine in patients with coronary artery disease limited by exertional angina pectoris.

Methods

Study patients: Ten men with documented coronary artery disease and exertional angina pectoris were studied (Table I); these patients were selected from a larger group of 20 consecutive patients with angina pectoris who were randomly allocated to this or a similar study on nifedipine. Patients with symptoms or clinical signs of congestive heart failure were excluded.

The aim of this study was carefully explained to the patients, and all gave consent. It was begun 1 week before or 1 week after the angiographic study; no complications occurred as a result of the experimental procedure.

Protocol: The patients first performed a multistage bicycle exercise test in the sitting position; the initial work load of 20 watts during 1 minute was increased by 20 watts every minute. Exercise was continued until the onset of typical angina pectoris; 1 minute samples of expiratory gases were collected during the last 3 to 4 minutes of the exercise (see later). Electrocardiographic leads V_4, V_5 and V_6 were monitored on an oscilloscope and recorded on paper every minute; a 12 lead electrocardiogram was recorded at rest, at peak exercise level and at the 2nd and 5th minutes of recovery. The electrocardiographic tracings were visually analyzed as previously described:[15] The amount of horizontal or downsloping S-T segment depression was measured in the most abnormal lead at the J point with the P-R level used as zero reference; the S-T segment abnormalities already present at rest were subtracted from the observed changes.

On the following day, hemodynamic measurements were taken (see later) with patients in the sitting position at rest and during two levels of exercise; each level lasted 4 to 6 minutes. The intensity of the first exercise level was well below the threshold of angina; the intensity of the highest exercise level was selected from the results of the first exercise test so that angina was induced after 3 to 4 minutes. Hemodynamic data were thus obtained at rest, during submaximal exercise and during exertion-induced angina. After completion of these measurements, the patients were given 2 mg of molsidomine intravenously and they rested in a supine position for 1 hour.

One hour after administration of molsidomine, the protocol was repeated. When angina was no longer precipitated at the work level that precipitated it before treatment with molsidomine, the hemodynamic measurements were performed at this level and the work load was then increased by 20 watts/min until angina pectoris or the first signs of exhaustion appeared; that level of exercise was maintained for 4 to 5 minutes until hemodynamic measurements were completed.

Hemodynamic measurements: Cardiac output was measured as previously described,[16] at rest and during the last minute of each exercise period using the Fick principle. Briefly, a 7 Swan-Ganz balloon-tip catheter was percutaneously introduced in the basilic vein and floated in the pulmonary artery; a small Teflon® catheter was introduced in the brachial artery. The pressures were measured during the 20 seconds preceding the cardiac output measurements with Statham P23Db transducers; the fourth intercostal space in the sitting position was the zero level. The expiratory gases were collected in neoprene bags; oxygen and carbon dioxide concentrations were determined as previously described[17] by a paramagnetic oxygen analyzer (Servomex OA 150) and by an infrared absorption carbon dioxide analyzer (Capnograph Godart 160). Expiratory volume was determined with a dry gas meter (Parkinson and Cowan, CD 4). The arterial and mixed venous oxygen contents were determined with a Lex-O_2CON analyzer.[18]

Precautions were taken to control the factors that might have influenced the response to exercise. The experiments took place in an air-conditioned room with temperature of 22° C (±1° C) and relative humidity of 50 percent (±10 percent). Before their first control exercise test, all patients had already performed at least one exercise test during the preceding weeks in the same room and with the same staff; the exercise studies reported here were all supervised by the same physician and the atmosphere of the laboratory was kept as quiet as possible.

The following hemodynamic variables were calculated: pressure-rate product: Heart rate × mean brachial pressure × 10^{-2}, expressed in mm Hg/min; *systemic and pulmonary resistances:* Mean pressure × 80/cardiac output, expressed in dynes/cm^{-5} per s; and *stroke work:* Stroke volume × mean brachial pressure × 1.36 × 10^{-2}, expressed in g-m.

Significances of differences were analyzed with the Student's paired *t* test.

* The higher control work load is simply due to the use of a different type of exercise test: stepwise (20 watts/min) increase in the work load during the control test and rectangular work loads for 4 to 6 minutes during the hemodynamic study.

B and A = before and after administration of molsidomine (hemodynamic study); C = control exercise test; NS = not significant; p = probability; S-L = symptom-limited.

Results

Exercise capacity: The individual data on maximal exercise capacity are presented in Table II. The symptom-limited oxygen consumption ($\dot{V}O_2$) and the maximal heart rate measured before administration of molsidomine during the hemodynamic study did not differ significantly from values measured during the first exercise test.

After molsidomine, the symptom-limited $\dot{V}O_2$ increased from 1,280 to 1,619 ml/min (+ 26 percent; $p < 0.02$), whereas the maximal heart rate was 15 beats higher (from 140 to 155 beats/min; $p < 0.02$). Angina was completely prevented in three patients and recurred at a higher exercise level in three other patients. The electrocardiographic abnormalities at the maximal exercise level were slightly but insignificantly lessened after molsidomine. A higher maximal work load after molsidomine was observed in six patients (Cases 5 to 10) whose average increase in physical working capacity was 44 percent (from 1,218 to 1,755 ml/min); four patients (Cases 1 to 4) had no change in physical capacity after administration of the drug. These four did not differ from the others with respect to age, history of myocardial infarction, number of diseased coronary vessels and ventricular function (Tables I and II).

Changes in hemodynamics at rest: The hemodynamic data are presented in Table III and Figure 1. At rest, in the sitting posture, the cardiac output averaged 4.9 liters/min and the mean cardiac index was 2.6 li

* $0.05 < p < 0.10$.

avO2 = arterial mixed venous oxygen difference (ml/100 ml); BaP = mean brachial arterial pressure (mm Hg); CO = cardiac output (liters/min); Δ = difference; HR = heart rate (beats/min); NS = not significant; p = probability; PaP = mean pulmonary arterial pressure (mm Hg); pressure-rate product = heart rate × mean brachial arterial pressure (mm Hg/min^{-2}); PVR = pulmonary vascular resistance (dynes sec cm^{-5}); ST↓ = S-T segment depression (mm); SV = stroke volume (ml/beat); SVR = systemic vascular resistance (dynes sec cm^{-5}); SW = stroke work (g·m) = stroke volume × mean brachial arterial pressure; $\dot{V}O_2$ = myocardial oxygen consumption (ml/min); WL = work load.

ters/min per m^2 (range 2.2 to 3.4). The mean pulmonary arterial pressure was 18 mm Hg and the pulmonary end-diastolic pressure 11 mm Hg (range 8 to 16 mm Hg).

After molsidomine (Table III, Fig. 1) cardiac output and stroke volume decreased whereas the heart rate increased; because the oxygen consumption was unchanged, the arteriovenous oxygen differences increased. The mean arterial and pulmonary pressures were lower but, because of the decreased cardiac output, the vascular resistances were unmodified. The stroke volume and the pressure-rate product were reduced after molsidomine.

Changes in hemodynamics at submaximal exercise: The changes observed after molsidomine during submaximal exercise were similar but less pronounced than those noted at rest (Table III, Fig. 1). Because the increase in heart rate was less (+9 beats/min) and the decrease in blood pressure was the same as at rest, the pressure-rate product was significantly decreased at submaximal exercise.

Changes in hemodynamics at maximal exercise: The work load causing angina pectoris in all patients in the control study was often (6 of 10 patients) performed after molsidomine without anginal pain. The prevention of angina pectoris was accompanied by significant decreases in pulmonary and mean arterial pressure, stroke work, pressure-rate product and systemic vascular resistance (Table III). The electrocardiographic signs of myocardial ischemia also tended to be reduced (difference not significant [NS]). The cardiac output and the heart were unmodified at that exercise level.

At the maximal exercise level, the increased oxygen consumption (+ 26 percent) was due to a greater cardiac output (+19 percent; p = NS; p <0.10) and to a wider arteriovenous oxygen difference (+6 percent). The mean arterial pressure remained slightly reduced after molsidomine and, accordingly, the peripheral vascular resistance was decreased; the mean pulmonary arterial pressure was slightly decreased (p = NS) and the pressure-rate product was insignificantly increased.

All the changes in mean pulmonary arterial pressure noted in this study closely reflected changes in the mean capillary wedge pressure or in the pulmonary end-diastolic pressure, or both. These variables decreased from 11.5 to 9.5 mm Hg at rest (p = 0.01; n = 9), from 18.5 to 13.5 mm Hg at submaximal exercise (p = 0.05; n = 6) and from 23 to 10 mm Hg at maximal exercise (p = NS; n = 4).

Discussion

Our data indicate that the effects of molsidomine in patients with coronary artery disease and angina pectoris are similar to those induced at rest and during

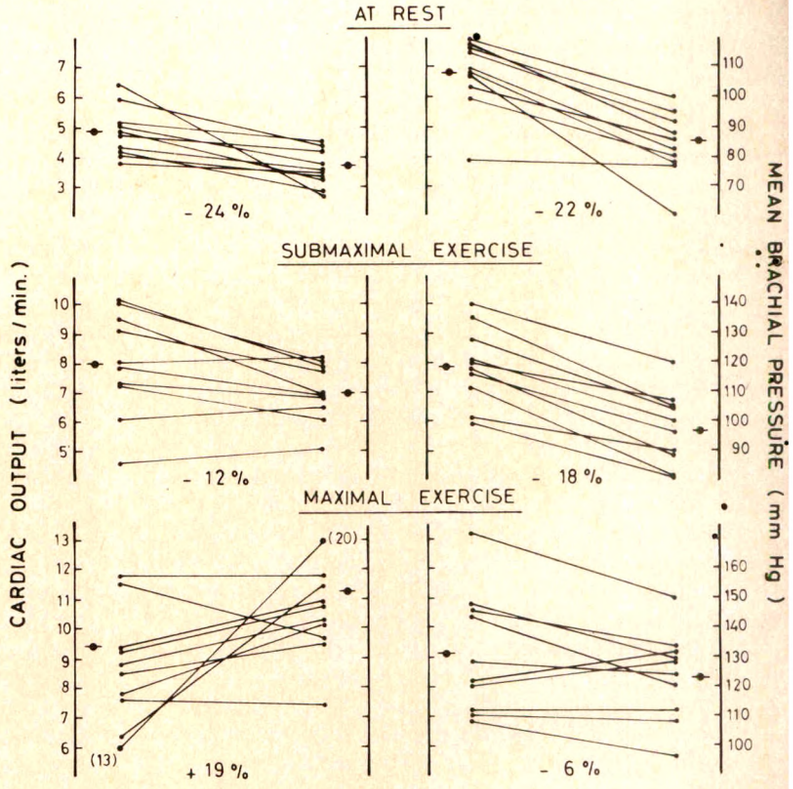

FIGURE 1. Cardiac output (**left panel**) and mean brachial pressure (**right panel**) in 10 patients at rest and during exercise before and after administration of 2 mg of molsidomine.

exercise by nitroglycerin or nitrates. These hemodynamic and clinical data were observed 1 hour after intravenous administration of 2 mg of molsidomine.

Reliability of the testing protocol: Our patients had severe coronary artery disease, indicated in all by angina pectoris and abnormal electrocardiographic responses to exercise. The diagnosis was ascertained in 9 of the 10 patients with angiographic data and in one patient with an abnormal thallium-201 scintigram demonstrating a permanent defect and a transient area of hypoperfusion. Their angina pectoris was stable and was induced at a highly reproducible heart rate and total level of oxygen consumption during two control exercise tests performed on consecutive days, the first without and the second with intravascular catheters. These patients had no signs of heart failure and their baseline hemodynamic data collected at rest and in a sitting posture are similar to those previously reported in patients with coronary artery disease and angina pectoris.[19]

The protocol of the hemodynamic studies included a first period of light exercise followed by a higher work load that induced angina pectoris in all patients in 3 to 5 minutes; this protocol is similar to that recommended by Redwood et al.[20] for studying the efficacy of a therapeutic intervention in patients with angina. With respect to cardiac output and measurements of stroke volume and central pressure during exercise, their reproducibility is good when the time elapsed between two exercise tests is long enough[17,21]; this time interval should not be less than 30 minutes and ideally should be 60 minutes in order to eliminate the hemodynamic modifications observed during repeated exercise.[17,22] Thus, the hemodynamic modifications observed in our study can safely be attributed to the effect of the drug and not to a placebo effect or the simple repetition of the exercise test.

Hemodynamic changes during exercise-induced angina: During exertional angina pectoris, most patients with coronary artery disease have clear signs of depressed left ventricular function as indicated by a marked elevation of the left ventricular end-diastolic pressure, pulmonary capillary wedge pressure or mean pulmonary arterial pressure.[26–29] These abnormalities, accompanied by a leveling or a decrease in stroke volume and stroke work, are similar to those observed during maximal exercise in patients with coronary artery disease not limited by angina pectoris;[16,30] however, in patients limited by angina, abnormalities occur at a decreased external work load and heart rate.[29] These hemodynamic abnormalities are caused by transient myocardial ischemia that depresses left ventricular function and probably also modifies left ventricular geometry, compliance and relaxation.[31–34] At a submaximal level of exercise, performed without pain, the hemodynamic response is intermediate and the importance of the hemodynamic disorders appears to be determined by the degree of left ventricular impairment at rest.[29,35,36]

Hemodynamic effects of molsidomine during rest and exercise: At rest and in a sitting posture, molsidomine decreased cardiac output and mean arterial and

pulmonary pressure in all our patients; these effects noted in patients with coronary artery disease without congestive heart failure confirm previous hemodynamic observations on molsidomine.[6–11] Thus, at rest, molsidomine seems to have a predominant action on venous return leading to a significant decrease in cardiac output accompanied by a reflex increase in heart rate. Systemic vascular resistances were not modified because at rest the decrease in cardiac output (−24 percent) was of the same magnitude as the decrease in mean arterial pressure (−22 percent). These changes are similar to those induced at rest by nitrates in patients without congestive heart failure.[21,27,28,37,38]

At submaximal exercise, the hemodynamic modifications noted after molsidomine were similar but clearly less marked than those at rest; the small decrease (−12 percent) in cardiac output indicated a persistent decrease in venous return, probably due to the dilating action of the drug on the venous wall. The intensity of the submaximal exercise level used in our study probably influenced the data because there was a progressive change in the hemodynamic effects of the drug from rest to maximal exercise, namely, a trend from a decrease in cardiac output at rest to an increase in cardiac output at the maximal exercise level. Had we used a submaximal exercise level of greater intensity, one can reasonably presume that the cardiac output would have been unchanged, as observed after administration of nitrates.[28,37,38]

Effects of molsidomine on angina pectoris and ventricular function: Our study includes hemodynamic data at the symptom-limited exercise level before and at that same level of exercise after administration of molsidomine. The prevention of angina pectoris in 60 percent of the patients after molsidomine was attended by a marked decrease in the mean pulmonary arterial pressure with no change in cardiac output; the mean arterial pressure was lower as were the systemic vascular resistances. The observed improvement in left ventricular function likely reflects a transient restoration or improvement of the equilibrium between the myocardial oxygen supply and requirements. Myocardial oxygen requirements are decreased (1) through a decrease in the mean arterial pressure and in the pressure-rate product, and (2) by a decreased left ventricular volume resulting from the reduced venous tone.[11] As a result, the hemodynamic and electrocardiographic alterations observed during angina pectoris were largely prevented and the majority of patients were able to exercise at higher external work loads before reonset of angina pectoris or until exhaustion without recurrence of anginal pain. Similar data have been collected after administration of nitrates.[21,25–28,40–45]

Mechanisms of action of molsidomine: After molsidomine, the physical capacity of our patients (as measured by symptom-limited oxygen consumption [$\dot{V}O_2$]) increased by 26 percent, which is similar to the antianginal effects noted by other investigators after administration of oral or sublingual molsidomine[2,3,5] and oral or sublingual nitrates.[2,3,5,23–25] This 26 percent increase in physical capacity is explained by a wider arteriovenous oxygen difference (+6 percent) and by a greater maximal cardiac output (+19 percent), which is associated with a higher maximal heart rate (+11 percent). At this postdrug maximal exercise level, the mean arterial pressure remained reduced (−6 percent) and the pressure-rate product tended to be increased (+4 percent). Other studies found that the antianginal action of molsidomine[3,4] or nitrates[23–25,39] was attended by a moderate increase in the maximal pressure-rate product. At this higher maximal exercise level, the effects of molsidomine on the venous tone are masked because, by definition, the increased maximal cardiac output postulates a greater venous return. The major mechanism of action of molsidomine at maximal exercise therefore appears to be a decrease in afterload, as suggested by lower systemic resistance. Both mechanisms (namely, decreased venous and arterial tone) are probably effective, but they mask each other in one direction at rest and in the opposite direction at maximal exercise. In any event, myocardial ischemia is delayed or prevented after drug administration.

Implications: After administration of molsidomine, 40 percent of our patients showed no improvement; the same observation has repeatedly been made with nitrates. The size of our group is insufficient to elucidate the reasons for the ineffectiveness of the drug in some patients, and these are now under study in a larger group of patients. We conclude that the acute hemodynamic effects of molsidomine are similar to those of nitrates and they imply a decrease in the venous tone as well as a lower peripheral arterial resistance. This drug deserves further study in both patients with angina and those with congestive heart failure.

Acknowledgment

We acknowledge the technical assistance of T.Berckmans and R. Vanbutselen and the helpful criticism of H. Pouleur, MD. We are grateful to the "Comptoir Chimico-Pharmaceutique" for providing molsidomine.

Hemodynamics at Rest and During Exercise After Oral Hydralazine in Patients With Cor Pulmonale

LEWIS J. RUBIN, MD*
ROBERT H. PETER, MD, FACC

Durham, North Carolina

Oral hydralazine has been shown to be effective in decreasing pulmonary arteriolar resistance and increasing cardiac output in some patients with primary pulmonary hypertension. To determine whether a similar response could be observed in patients with chronic cor pulmonale, the hemodynamic status before and after the oral administration of hydralazine (25 mg, then 50 mg every 6 hours for 48 hours) were evaluated in 12 patients at rest and in 8 during upright exercise. After hydralazine, there was an increase in cardiac output at rest, from 4.3 to 6.3 liters/min ($p < 0.001$), and reductions in arteriovenous oxygen difference, from 8.1 to 6.1 volume percent ($p < 0.001$), mean pulmonary arterial pressure, from 52 to 44 mm Hg ($p < 0.01$), and pulmonary arteriolar resistance, from 11.2 to 6.2 units ($p < 0.0005$). Similar hemodynamic changes occurred during exercise, including an increase in pulmonary arterial saturation from 27 to 39 percent ($p < 0.001$) and a decrease in total pulmonary resistance from 12.7 to 8.9 units ($p < 0.01$). Results of pulmonary function tests performed before and after hydralazine did not change with drug administration. These findings indicate that the lung vascular bed in some patients with cor pulmonale is capable of responding to hydralazine with a reduction in pulmonary resistance and an increase in cardiac output both at rest and during exercise.

Pulmonary hypertension can complicate various forms of chronic lung disease and, next to coronary artery disease and hypertensive cardiovascular disease, cor pulmonale is the most common cardiac disorder beyond the 5th decade of life.[1] The treatment of cor pulmonale has primarily been aimed at optimizing intrapulmonary gas exchange with bronchodilators, corticosteroids, antibiotic agents and chest physiotherapy. Supplemental oxygen therapy causes a reduction in pulmonary arterial pressure in some patients with hypoxemia and cor pulmonale,[2–4] but the responsiveness of the pulmonary vascular bed to increased concentrations of inspired oxygen tends to diminish with prolonged use.[5] Diuretic drugs, often used to reduce preload and edema,[6] can cause metabolic derangements that are poorly tolerated by patients with pulmonary disease.[7,8] Although cardiac glycosides have been recommended for right ventricular failure,[9] the limited clinical response and the increased risk of toxicity associated with their use in the setting of chronic pulmonary disease make their role controversial.[10]

Vasodilators have been used for many years to treat systemic hypertension, and in the last few years have gained acceptance for treatment of left ventricular failure. Attention has recently been paid to the usefulness of some vasodilators in treating idiopathic pulmonary hypertension.[11] However, there is little experience with these drugs in treating pulmonary hypertension secondary to chronic lung disease. This study evaluates the effects of oral hydralazine on the hemodynamic status at rest and during exercise in patients with cor pulmonale, to determine the potential usefulness of this drug as an adjunct to the conventional therapy of pulmonary heart disease.

Methods

Study patients: Twelve patients with stable chronic lung diseases and pulmonary hypertension were evaluated between November 1977 and April 1980. On the basis of the clinical data (Table I), the patients were classified as having one of three types of ventilatory defect: obstruction, restriction or mixed obstruction and restriction. Four of the five patients with obstructive airways disease had chronic bronchitis and one patient had asthma. Both patients with a restrictive ventilatory defect had interstitial pulmonary fibrosis, which was documented by lung biopsy. One of the patients with a mixed ventilatory defect had scleroderma in addition to chronic bronchitis, one had chronic bronchitis and a history of tuberculosis for which he had undergone a thoracoplasty 30 years previously, two patients had a mixed defect from undetermined causes, and one patient had sarcoidosis. None of the 12 patients had a history of myocardial infarction or known coronary artery disease. All of the patients underwent routine pulmonary function studies during a stable period in their course. The testing procedures used and the predicted normal values derived for each patient followed the accepted guidelines for pulmonary function testing.[12]

All of the patients were treated with conventional therapy for at least 6 months before the study. This therapy was continued unaltered during the period of hospitalization. Supplemental oxygen therapy was discontinued just before and throughout each cardiac catheterization procedure. Treatment consisted of administration of bronchodilators, antibiotic agents, supplemental oxygen, corticosteroids, diuretic drugs and digitalis compounds, as each patient's clinical status indicated. No patient had an acute respiratory or cardiac condition at the time of study or a history of previous myocardial infarction. None had valvular heart disease or clinical left ventricular failure. Informed consent, in compliance with the Medical Center Committee for Clinical Investigations, was obtained from each patient before the study.

Hemodynamic measurements: Right heart catheterization was performed using a balloon-tipped flotation catheter inserted into an antecubital or internal jugular vein. A plastic catheter was inserted into a brachial or radial artery for recording systemic pressure and sampling arterial blood. Measurements of supine right atrial, right ventricular, pulmonary arterial and pulmonary capillary wedge pressures were made by averaging the values over at least three respiratory cycles. Mean pressures were calculated by adding one third of the pulse pressure to the diastolic pressure. Timed collections of exhaled volume during tidal breathing were measured in a gasometer and the volumes converted to STPD (standard temperature and pressure, dry). The oxygen content of the exhaled gas was measured using a paramagnetic oxygen analyzer (Beckman Instruments), and from these data, we calculated total body oxygen consumption. Simultaneous arterial and mixed venous blood samples were collected anaerobically in heparinized syringes and their oxygen contents were determined using an IL-282 Co-oximeter (Instrument Labora-

avO_2 = arteriovenous oxygen difference; BA = brachial arterial pressure; BA Sat = brachial arterial saturation; C = control, CO = cardiac output; H = hydralazine; HR = heart rate; NS = not significant; p = probability; PA = pulmonary arterial pressure (systolic and diastolic with mean in parentheses); PAR = pulmonary arteriolar resistance; PA Sat = pulmonary arterial saturation; PCW = pulmonary capillary wedge pressure; RA = mean right atrial pressure; RVEDP = right ventricular end-diastolic pressure (in the supine position); TPR = total pulmonary resistance; TSR = total systemic resistance; $\dot{V}O_2$ = total body oxygen consumption.

tories). Cardiac output was calculated using the Fick equation.

Exercise testing: Eight of the patients were also studied at rest in the sitting position and during a period of exercise. After measurements in the supine position were made, each of these patients was placed in the sitting position on a bicycle ergometer. The pressure transducer level was adjusted to the reference point of zero pressure and the transducer height was recorded so that an identical level would be used for each patient's repeat study. Systemic and pulmonary arterial and pulmonary capillary wedge pressures and cardiac output were measured during seated rest. The patient then pedaled the bicycle for 3 minutes at 150 kilopond-meters/hour, and pulmonary and systemic arterial pressures and cardiac output were measured during the final minute of exercise. Previous experience in our laboratory has demonstrated that this degree of exercise causes at least a doubling of the oxygen consumption at rest.[13,14]

Hydralazine therapy: After the initial cardiac catheterization, the patients were immediately given 25 mg of hydralazine orally. When this dose was tolerated without significant adverse effects, they were then given hydralazine, 50 mg orally every 6 hours. Hemodynamic studies were repeated 48 hours after beginning therapy with hydralazine. The last dose of hydralazine before restudy was always given 1 to 2 hours before cardiac catheterization. Systemic and pulmonary vascular resistance were calculated using the standard formulas. Heart rate was obtained from a continuously monitored electrocardiogram. Statistical analysis of the data was performed with use of Student's two-tailed t test for paired data.

Results

Hemodynamic data at rest (Table II): All 12 patients had elevated pulmonary arterial pressure and pulmonary arteriolar resistance. The patients with either a pure restrictive ventilatory defect or a mixed ventilatory defect had higher pulmonary arterial pressure than most patients with obstructive airways disease alone. The control arteriovenous oxygen difference was abnormal in 11 of the 12 patients, reflecting an inadequate cardiac output for the tissues' oxygen demands. Eight patients had elevated right ventricular end-diastolic pressures and three of these had clinical findings of right ventricular failure. Pulmonary capillary wedge pressure at rest was normal in all patients.

After the administration of hydralazine, there were statistically significant decreases in the mean pulmonary arterial pressure ($p < 0.01$), arteriovenous oxygen difference ($p < 0.001$) and pulmonary arteriolar and total pulmonary resistances ($p < 0.0005$). Cardiac output was increased and heart rate was not significantly changed. Mean stroke volume increased 40 percent. Systemic arterial pressure did decrease significantly, but without any adverse effects.

Hemodynamic data during exercise (Table III): Mean pulmonary arterial pressure increased in the eight patients studied during exercise, and this increase was significantly blunted by hydralazine. Although cardiac output increased with exercise relative to control values at rest, the arteriovenous oxygen difference was markedly increased for this degree of mild exercise. After hydralazine, cardiac output was significantly increased during exercise ($p < 0.05$), and stroke volume increased

by 30 percent. Mean systemic blood pressure and heart rate were not appreciably changed. The arteriovenous oxygen difference narrowed, and the total pulmonary resistance was decreased. Whereas pulmonary capillary wedge pressure could be obtained from only five patients during exercise (Cases 1, 3, 6, 7 and 12), the values remained within the normal range (mean 14 mm Hg).

Discussion

Hemodynamic improvement after hydralazine in cor pulmonale: Hydralazine is used to treat left ventricular failure because it decreases left ventricular afterload. Systemic resistance decreases and cardiac output increases and there is usually little change in systemic blood pressure in this setting.[15,16] However, in patients with systemic hypertension both systolic and diastolic blood presssure decrease. Our experience with hydralazine for primary pulmonary hypertension[14] suggested that patients with other disorders characterized by an increased afterload to the right ventricle, such as cor pulmonale, might obtain beneficial results with this drug in a manner analagous to that of patients with systemic hypertension or left ventricular failure. Our 12 patients with parenchymal lung disease and pulmonary hypertension showed an increased oxygen delivery to the tissues at a lower right ventricular afterload both at rest and during exercise after being treated with oral hydralazine. None manifested adverse effects that limited the drug's use. These observations are consistent with the hypothesis that hydralazine caused vasodilatation of the pulmonary resistance vessels, thereby reducing impedance to right ventricular

flow and leading to an increased right ventricular output and peripheral oxygen delivery.

Patients who have left ventricular failure,[13,15–17] aortic insufficiency[18] or mitral insufficiency[19] with or without left ventricular dysfunction often manifest a reduction in the left ventricular filling pressure with hydralazine. Vasodilator therapy with hydralazine, for unclear reasons, may also cause a reduction in left ventricular end-diastolic pressure in some patients with mitral insufficiency.[19] It is possible that the small but statistically significant decreases in both mean right atrial and right ventricular end-diastolic pressures that we observed in our patients are a result of a decrease in tricuspid or pulmonary valve regurgitation secondary to pulmonary vasodilatation with hydralazine.

Several studies have demonstrated that the degree of pulmonary hypertension remains stable for prolonged periods of time in patients with cor pulmonale and stable respiratory function.[5,20,21] We therefore think it is likely that the hemodynamic improvement after 48 hours of hydralazine therapy was the result of this therapy in our patients with stable lung disease maintained on their previous regimen. The reduction in systemic arterial pressure and resistance after beginning hydralazine is consistent with the known systemic effects of this drug, but in the absence of left ventricular dysfunction, it was not the cause of the hemodynamic improvement we observed.

Role of vasodilation in pulmonary vascular disease and vasoconstriction: Some investigators have stressed the significance of the diminished pulmonary vascular bed in the development of pulmonary hypertension in obstructive[22] as well as restrictive[23] lung disease. Our demonstration that some patients with diverse causes for pulmonary hypertension, even those with interstitial pulmonary fibrosis, respond to vasodilator therapy suggests that there may be reversible constriction in addition to the restriction of the pulmonary vascular bed in this setting. If the cardiac output had increased and the pulmonary resistance decreased as a result of increased intrapulmonary shunting after hydralazine, arterial oxygenation would have decreased significantly; arterial oxygenation was not appreciably changed in our patients.

One major concern about vasodilator therapy for chronic cor pulmonale is the possibility of causing vasodilatation in areas of poor alveolar ventilation. This effect could worsen the hypoxemia of chronic lung disease by exaggerating the ventilation/perfusion imbalance already present. This phenomenon has been implicated in the increased alveolar/arterial oxygen gradient observed in patients receiving nitroglycerin[24] or nitroprusside.[25] However, the arterial oxygen contents were not appreciably changed by hydralazine in our patients, thus suggesting that the increased pulmonary blood flow, coupled with the greatly improved mixed venous saturation, offset any potential aggravation of ventilation perfusion mismatching. The contribution of a low mixed venous saturation to the development of hypoxemia in obliterative pulmonary vascular disease was recently emphasized by Dantzker and Bower.[26]

Hydralazine is a vascular smooth muscle relaxing agent, and we reasoned that it might also be a bronchial smooth muscle dilator as well. However, pulmonary function studies performed before and after hydralazine therapy failed to show any change in air flow rates.

Implications: The survival of patients with chronic pulmonary disease has been linked by several studies to the presence and degree of pulmonary hypertension.[20,27–29] Whether the use of effective vasodilators will alter the course of cor pulmonale is not known, but these agents may prove useful in its management.

Clinical Pharmacology and Antiarrhythmic Efficacy of N-Acetylprocainamide

ROGER A. WINKLE, MD, FACC*
PATRICE JAILLON, MD*
ROBERT E. KATES, PhD
FLORA PETERS, RN

Stanford, California

Eleven patients with chronic ventricular arrhythmias took part in a study of N-acetylprocainamide (NAPA), the major metabolite of procainamide, in order to characterize further NAPA's clinical pharmacology and antiarrhythmic action. The frequency of ventricular arrhythmia on 24 hour ambulatory electrocardiographic recordings was comparable on recordings obtained in a prestudy screening, during treatment with placebo before administration of NAPA and after treatment with NAPA. The initial dosage of NAPA was 500 mg every 8 hours, which was increased by 500 mg increments every few days until 90 percent suppression of arrhythmia or intolerable adverse effects occurred. Only two patients achieved 90 percent suppression of ventricular ectopic complexes. The mean plasma concentration associated with 90 percent suppression of arrhythmia in these two patients was 12.6 and 32.3 mg/ml, respectively. One of these two patients was unable to continue long-term therapy with NAPA because of a rash. Other adverse effects included gastrointestinal symptoms in seven patients with visual symptoms in four patients at plasma concentrations as low as 6.9 mg/ml. NAPA obeyed linear pharmacokinetics over the range of dosages studied (500 to 2,500 mg every 8 hours) and had a half-life of 10.7 ± 1.98 hours (mean ± standard deviation). There was no change in the P-R or QRS intervals and there was a dose-dependent prolongation of the Q-Tc interval. It is concluded that in this patient group, NAPA suppressed chronic ventricular ectopic complexes without adverse effects in only a minority of patients.

N-acetylprocainamide (NAPA) is the major metabolite of procainamide in human subjects.[1] Pharmacokinetic studies have shown that this compound is well absorbed after oral dosing, is primarily eliminated by the kidneys and has a longer half-life than procainamide.[2–6] Electrophysiologically NAPA differs from procainamide in that it does not alter His-Purkinje conduction times at clinically tolerated plasma concentrations.[7,8] Preliminary studies indicate that NAPA has an antiarrhythmic action in human subjects after single[9] or multiple doses[10–12] and that long-term oral therapy is possible.[13] Evidence to date[11,13,14] indicates that long-term therapy with NAPA is less likely than procainamide to cause systemic lupus erythematosus. This study was undertaken to investigate further the antiarrhythmic activity, adverse effects and pharmacokinetics of NAPA in patients with chronic stable ventricular arrhythmias.

Methods

Study patients: Eleven patients, nine men and two women, with a mean age of 58.3 ± 11.6 years (range 42 to 75) participated in this study. Each patient had frequent and complex ventricular arrhythmias believed by their referring physician to require antiarrhythmiac therapy. The protocol was approved by the Stanford Human Subjects Committee and each patient gave written informed consent. Each patient's underlying heart disease is listed in Table I. Eight patients had documented coronary artery disease, two had presumed coronary artery disease and one patient had mitral valve prolapse. Patients with severe

hepatic or renal disease or uncompensated congestive heart failure were excluded from this study.

Protocol design: Each patient underwent a baseline 24 hour ambulatory electrocardiographic recording to determine suitability for the study. These baseline recordings were performed with all but one patient taking no antiarrhythmic agents; the latter patient (Case 11) was taking propranolol for angina. Patients averaging at least one premature ventricular complex per minute over 24 hours were started on an initial 24 hour placebo period with one placebo tablet (identical in appearance and taste to the 500 mg NAPA tablets) taken every 8 hours. During this placebo period each patient had another 24 hour ambulatory electrocardiogram recorded. Patients were then started on 500 mg of NAPA every 8 hours and maintained on this dosage for a minimum of 3 days to allow attainment of steady state plasma drug concentrations. Each patient then underwent another 24 hour electrocardiographic recording; blood samples were taken using a heparin lock in a peripheral arm vein over an 8 hour dosing interval at the following times: immediately before administration of the drug and 30, 60, 90, 120, 180, 240, 360 and 480 minutes after each dose. An assessment of adverse effects was made for each dose by use of a standard questionnaire and by direct patient interview. Ambulatory electrocardiographic recordings were promptly processed. If there was neither a 90 percent reduction in arrhythmia compared with the frequency during the period of placebo administration nor intolerable drug adverse effects, the NAPA dose was increased by 500 mg every 8 hours (1.5 g daily) and patients were maintained on this larger dose for at least three additional days to allow attainment of new steady state plasma concentrations. Twenty-four hour ambulatory electrocardiographic recordings and blood sampling over one 8 hour dose interval were again performed. This sequence was repeated until 90 percent suppression of arrhythmia or intolerable adverse effects occurred.

Once one of these end points was reached, patients underwent blood sampling during NAPA drug withdrawal in order to measure the drug's half-life. Blood samples were obtained using a heparin lock in a peripheral vein immediately before and at the following times after the last dose of NAPA: 30, 60, 90 and 120 minutes; 3, 4, 6, 8, 12, 16, 24, 36, 48, 60 and 72 hours. After drug withdrawal another ambulatory electrocardiographic recording was recorded for each patient in order to obtain a final baseline value for arrhythmia frequency without NAPA. Twelve lead electrocardiograms were obtained before entry into the study and at steady state plasma concentrations of each NAPA dose tested. These electrocardiograms were used to determine R-R, P-R, QRS and Q-T intervals (corrected for heart rate according to the Bazett formula).[15] Each patient underwent a battery of routine laboratory safety tests before and after participation in this study. Patients with greater than 90 percent reduction of frequency of ventricular ectopic complexes and without intolerable adverse effects were treated with long-term oral NAPA therapy.

Plasma concentration measurements: Five milliliters of blood was withdrawn and placed in heparinized tubes for each determination of NAPA plasma concentration. Plasma was separated by centrifugation and frozen until analysis. The plasma concentrations of NAPA were determined by a specific high pressure liquid chromatography assay modified with ion paired chromatography. Drugs were extracted from plasma into ethyl acetate after buffering with sodium bicarbonate at pH 10. The lower limit of sensitivity of the assay was 0.1 μg/ml. Mean plasma concentration over a dosing interval was determined by dividing the area under the plasma concentration time curve over one dosing interval by the duration of the dosing interval (8 hours). Half-life was determined by the log-linear least-squares best fit of the concentration versus time data between 8 and 72 hours after the last dose. To determine whether a steady state was achieved with each dose, the plasma concentrations immediately before the dose and at the end of the dosing interval were compared using a matched paired t test.

Ambulatory electrocardiographic analysis: Ambulatory electrocardiographic recordings were analyzed using the Stanford computerized ambulatory electrocardiographic analysis system.[16] This system provides an exact count of all premature ventricular complexes defined by the operator as wide QRS complexes that are premature and not preceded by apparent P wave activity. The computer classifies ectopic complexes by morphology and allows determination of the number of foci of ectopic complexes, the number of episodes of ventricular tachycardia (defined as three or more ventricular ectopic complexes in a row), the number of pairs of such complexes and the number of episodes of ventricular bigeminy occurring on a tape. The accuracy of analysis is checked individually for each tape by operator-editing of complexes in

each family and by sampling random minutes throughout the recording as well as minutes determined by the computer to have ectopic complexes and each type of complex ventricular arrhythmia and performing a complex by complex comparison of computer classification and operator classification. The Wilcoxon rank sum nonparametric statistical technique was used to compare the frequency of ventricular ectopic complexes on 24 hour ambulatory electrocardiographic recordings in the baseline and placebo periods and in each of these periods and the final post-study period.

Results

NAPA Plasma Concentrations

The plasma concentrations achieved for each subject on each NAPA dose are given in Table II. For each dose there was no statistically significant difference between the plasma concentration before the dose and that at the end of the dosing interval, indicating that sufficient time had elapsed during dosing to achieve steady state plasma concentrations. The mean (± standard deviation) plasma concentration immediately before the NAPA dose ranged from 5.43 ± 2.25 μg/ml for the 500 mg dose to 21.0 ± 3.37 for the two patients receiving the highest dosage of 2,500 mg every 8 hours. The peak plasma concentration occurred from 1.3 to 2.2 hours after the drug was given and ranged from 1.6 to 1.8 times the predrug "trough" level. The average plasma concentration over a dosing interval for the entire group of patients ranged from 7.03 ± 2.41 μg/ml at the 500 mg dose level to 29.6 ± 3.75 μg/ml in the two patients receiving the highest dosage. Figure 1 shows the average plasma concentration over a dosing interval as a function of administered dose for each of the nine subjects having mean plasma concentrations measured at more than one drug dose. For each patient there was an approximately linear relation between mean plasma concentration and drug dose suggesting that NAPA has linear pharmacokinetics over the range of doses studied. Half-life. (Table II) after drug withdrawal was determined in seven patients and averaged 10.70 ± 1.98 hours (range 8.0 to 14.0).

Antiarrhythmic Efficacy

Table III shows the average number of premature ventricular complexes/hour in each 24 hour ambulatory electrocardiographic recording.

Individual patient responses. Table IV shows the percent change in frequency of ventricular ectopic complexes for each NAPA dose in each patient compared with the frequency in the pre-NAPA placebo period. Only two patients achieved 90 percent reduction in frequency of ectopic complexes used to define indi-

idual responders to NAPA. In one of these patients (Case 4) the reduction was definitely considered a result of treatment with NAPA. The reduction in ventricular ectopic complexes was dose-dependent, with a 93 percent decrease achieved with the dosage of 1,500 mg every 8 hours and return of the ectopic complexes in the post-NAPA 24 hour recording. Unfortunately this patient was unable to continue on long-term therapy because of a severe rash.

Patient 3 also had a greater than 90 percent reduction of ectopic complexes with NAPA, achieving a 93 percent decrease with the 1,500 mg dose level of NAPA. However, it was initially not clear that this represented a true drug response because the patient had shown an 86 percent spontaneous reduction (from 60 to 8.2/hour) in arrhythmia frequency between the placebo and initial baseline recordings. After 1,500 mg dosage of NAPA was withdrawn, the ectopic complex frequency increased to 15.37/hour, then decreased to almost 0 with reinstitution of NAPA. On the basis of this finding the patient was considered a NAPA responder and has subsequently been receiving maintenance therapy with the drug for more than 1 year. He has continued to show almost no ectopic complexes on sequential ambulatory electrocardiographic recordings, has had a marked reduction in symptoms of palpitations and has maintained a negative fluorescent antinuclear antibody test. The NAPA plasma concentration associated with 90 percent reduction in these two patients was, respectively, 12.6 (Case 3) and 32.3 (Case 4) μg/ml.

Group responses: The average number of ventricular ectopic complexes/hour during the initial baseline recording was 429 ± 385. This value is not statistically significantly different from the 586 ± 501/hour recorded during the pre-NAPA placebo period. Nine patients underwent repeat ambulatory monitoring after withdrawal of NAPA therapy and had an average of 388 ± 390 complexes/hour. This number was not statistically significantly different from that in the baseline and placebo recordings. Thus there did not appear to be a significant trend toward an increase or decrease in average frequency of ventricular arrhythmia in this group of patients during the course of this study.

Ten patients received the 500 mg dose and 10 received the 1,000 mg dose every 8 hours. There was no statistically significant reduction of ventricular ectopic complexes with either dose (average hourly frequency of ectopic complexes of 400 ± 281 and 390 ± 292, respectively). Because of the high incidence of adverse effects fewer numbers of patients received the 1,500, 2,000, and 2,500 mg doses of NAPA. There did not seem to be a readily apparent group reduction in ectopic complex frequency in patients tolerating the larger doses (Table III). Examining ventricular ectopic frequency as a function of plasma concentration rather than of dose showed a slight trend toward suppression at concentrations above 24 μg/ml (Fig. 2). Just as the total number of ventricular ectopic complexes did not seem to be markedly reduced for the group, complex forms of ectopic complexes (quantitatively described as number of episodes of pairs, runs and bigeminy and

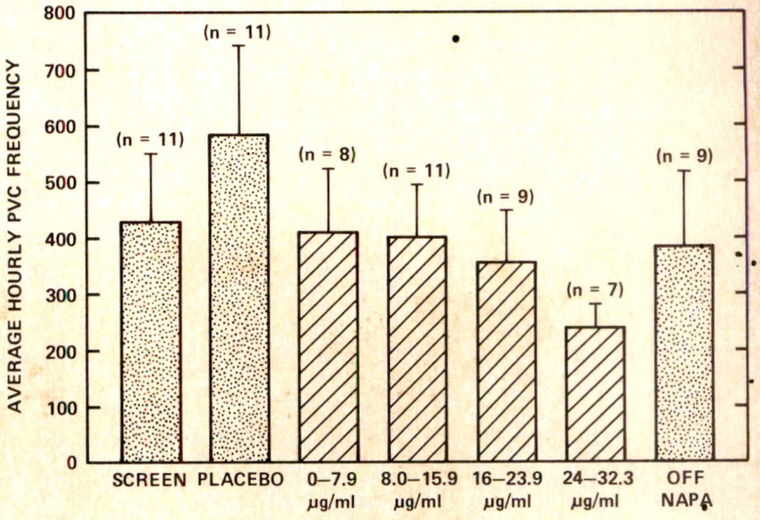

FIGURE 2. Average hourly frequency of premature ventricular complexes (PVC) (± standard error of the mean) seen on ambulatory electrocardiographic recordings on the initial screening test, during the predrug placebo period, during therapy with NAPA at various doses and at the end of the study after withdrawal of NAPA. Shown also are the group average serum concentration-response data for NAPA. Although there was a suggestion of a reduction of ventricular arrhythmias above a concentration of 24 μg/ml the decrease was not striking. n = the number of 24 hour recordings in each category.

number of morphologies present on each 24 hour recording) were not greatly affected by therapy with NAPA.

Electrocardiographic Findings

Table V summarizes the average interval measurements in the 12 lead electrocardiogram made on each dose of NAPA. There were no significant changes in P-R or QRS intervals. There was a suggestion of a dose-dependent prolongation of the R-R interval from 840 ± 155 ms in the control recording to 900 ± 109 ms with the dose of 2,000 mg. Although this trend in cycle length was noted for the averaged group data, it was not readily apparent for any individual patient. There was a definite dose-dependent prolongation of the Q-Tc interval for both individual patients as well as for the group average (Fig. 3). One patient had an intraventricular conduction defect and another had intermittent right bundle branch block before NAPA therapy and neither had these abnormalities worsened with NAPA.

Adverse Effects

Adverse gastrointestinal effects occurred most frequently (7 of the 11 patients). Most patients described a sensation of nausea or a "queasy" stomach with one subject also vomiting and two others having associated diarrhea. Several patients initially had mild gastrointestinal symptoms, but with larger drug doses the adverse effects worsened in all cases. The mean plasma concentration associated with the onset of gastrointestinal symptoms in these seven patients was respectively, 6.9, 7.9, 8.5, 18.4, approximately 20 to 22, 25 and 25.6 μ/ml.

Four patients complained of visual symptoms including "blurred" vision (three patients) and "flashes" or "wavy" vision (one patient). The latter subject was noted to have bilateral vitreous detachments without permanent sequellae. Although two independent consultant ophthalmologists did not believe that the latter patient's symptoms were due to NAPA, we cannot fully exclude that possibility.

One patient (Case 4) experienced an allergic reaction that was believed to be due to NAPA. This patient had the most striking antiarrhythmic response to NAPA and was to have received long-term oral therapy with the drug. After 15 days of NAPA therapy he exhibited a diffuse pruritic urticarial rash that was most prominent over his trunk and buttocks. Administration of the drug was stopped immediately, and the rash promptly resolved. Because there was modest circumoral edema it was decided not to rechallenge the patient. A careful history revealed no other potential cause for the rash.

One patient died while taking part in this study. He was a 68 year old man with coronary artery disease and

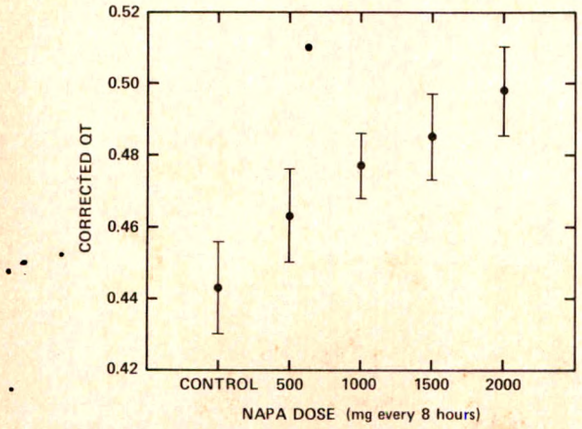

FIGURE 3. Average Q-Tc interval (± standard error of the mean) as a function of the dose of NAPA. This dose-dependent Q-Tc prolongation was also seen in each individual patient.

moderately well compensated congestive heart failure. He had a long history of complex ventricular arrhythmia including frequent brief runs of ventricular tachycardia causing palpitation but never dizziness or syncope. He had no change in his arrhythmias or marked change in the Q-T interval with the 500 or 1,000 mg dose of NAPA. After 3 days on the 1,500 mg dose he died suddenly without experiencing any untoward symptoms. It seems most likely that his death was related to his underlying heart disease. Although NAPA clearly failed to prevent his death, there is no compelling reason to suspect that it contributed to it, although we cannot exclude that possibility.

Discussion

Our experience with n-acetylprocainamide (NAPA) in this protocol was disappointing. We were able to achieve 90 percent suppression of ventricular ectopic complexes in only 2 of 11 patients. We chose 90 percent reduction of ventricular ectopic complexes in order to avoid the possibility of classifying a spontaneous decline of ventricular arrhythmias as a response to NAPA.[17,18] Lowering our criterion for defining drug responders to as low as 70 percent reduction would have had little effect on the overall results of this study. Whereas the patient group studied did include patients referred because their arrhythmias were difficult to suppress with more standard agents, it is not dissimilar from that which we have utilized for other antiarrhythmic drug studies.[19–21] In fact, several patients unsuccessfully treated with NAPA have subsequently had arrhythmias successfully suppressed with other new compounds.

Comparisons with previous studies: Superficially, our experience with NAPA seems less encouraging than that reported from other centers. Lee et al.[9] reported on the antiarrhythmic response to a single oral dose of 1.5 g of NAPA. They concluded that six of nine patients responded to NAPA. However, three of these six had very transient reductions in the frequency of ventricular ectopic complexes, which could have been due to spontaneous variations. Only three of the nine had a marked and sustained suppression of the type one must observe during acute drug testing to be confident of drug effect.[22] Atkinson et al.[10] performed a NAPA dose-ranging study in 10 patients with chronic ventricular ectopic complexes. Only four patients achieved greater than 80 percent reduction in a 6 hour electrocardiographic recording and one of these had no return of ectopic complexes after administration of the drug was stopped. Woosley et al.[11] found that only 7 (32 percent) of 22 patients had reproducible reduction of ventricular ectopic complexes with NAPA at plasma concentrations ranging from 8 to 18 μg/ml. Kluger et al.[12] found that 9 of 15 patients had a greater than 50 percent reduction of ventricular ectopic complexes in a 24 hour electrocardiographic recording. The use of a 50 percent reduction response criterion suggests that the actual number of true drug responders may have been less than nine.[18] Taken as a whole, these studies, when combined with ours, suggest that approximately one third of patients may be expected to have significant suppression of ventricular ectopic complexes while taking oral NAPA.

Adverse effects: Other studies have reported adverse effects from NAPA similar to those found in our study. Atkinson et al.[10] found that 40 percent of patients had adverse effects during a brief dose-ranging period. These effects included nausea, anorexia, emesis, diarrhea and insomnia. Kluger et al.[12] noted 44 percent of patients to have adverse effects. The higher incidence of such effects in our study was in part due to the protocol design that called for increasing the dose of NAPA until either adverse effects or 90 percent reduction of premature ventricular complexes occurred. However, in several instances we observed side effects at plasma concentrations of less than 10 μg/ml. For NAPA it seems that there is considerable overlap between plasma concentrations at which side effects occur and those at which antiarrhythmic efficacy is observed. Thus it would be expected that many of the patients who do have antiarrhythmic response to NAPA might not be able to continue long-term therapy because of adverse effects.

Electrophysiologic effects: The observations that NAPA prolonged the Q-Tc interval but did not alter the P-R interval and QRS duration and that the condition of patients with abnormalities of His-Purkinje conduction did not worsen during NAPA therapy are compatible with the drug's known electrophysiologic action. In isolated Purkinje fibers[23] the drug does not alter the phase 0 upstroke or phase 4 depolarization but does prolong action potential duration. In both dogs[7] and human beings[8] we have shown that intravenous NAPA has no consistent effect on intraventricular or His-Purkinje conduction times but does prolong ventricular refractoriness and Q-T intervals. The lack of action on His-Purkinje conduction at clinically tolerated plasma concentrations makes the drug electrophysiologically different from procainamide.

Pharmacokinetics: Our study demonstrates that NAPA obeys linear pharmacokinetics over the clinically

tolerated range of oral doses. Thus, for any change in the dose of NAPA there will be an equivalent proportional change in steady state plasma concentration. The average half-life of 10.7 hours in our study is longer than the half-life of 6.2 hours reported by Atkinson et al. in normal subjects[5] but similar to the half-life of 10.9 hours they found in patients with ventricular arrhythmias.[10]

Therapeutic implications: The data from our and other studies of NAPA have implications for the use of oral procainamide. The different electrophysiologic actions of procainamide and NAPA imply that antiarrhythmic response to one compound will not guarantee response to the other, a finding recently confirmed in human subjects by Woosley et al.[11] Because significant antiarrhythmic effect is not consistently observed in patients receiving NAPA and may occur only at NAPA plasma concentrations higher than those usually occurring during long-term dosing with procainamide (in subjects without renal failure), the antiarrhythmic action of NAPA may have little to do with the antiarrhythmic response observed during long-term therapy with procainamide. Certainly one cannot advise patients to take procainamide less frequently than every 4 hours or to omit doses of procainamide in the middle of the night with the expectation that NAPA will provide continuing antiarrhythmic action after procainamide plasma concentrations are subtherapeutic. Although many laboratories are now reporting procainamide and NAPA plasma concentrations, for most patients the clinical value of knowing the NAPA concentration would seem to be minimal. In any patient one could not predict whether NAPA and procainamide might have antiarrhythmic actions that are synergistic, competitive or bear no relation to one another. Finally, it seems likely that some of the adverse gastrointestinal effects seen during oral procainamide therapy may result from NAPA rather than from procainamide. This would be most likely to occur during administration of large doses of procainamide or in patients with renal impairment in whom high NAPA levels may occur[3,4] but occasionally might occur in rapid acetylators receiving standard doses of procainamide.

The ultimate role of NAPA remains to be defined. Whereas it clearly has antiarrhythmic actions in some patients with ventricular arrhythmias, in our experience it seems less effective than other available and investigational drugs for suppression of ventricular ectopic complexes. Its high rate of adverse effects would seem to be a drawback to its widespread clinical use. Because it is not a direct substitute for procainamide, much of the value of its lack of induction of systemic lupus erythematosus seems to be lost because patients responsive to procainamide cannot necessarily be switched successfully to NAPA. Its long half-life permits a reasonable dose interval and its lack of effect on the cardiac conduction system may offer some advantages in patients with atrioventricular nodal or His-Purkinje disease. The drug's reported lack of myocardial depressant effect[10] may also have advantages in patients with compromised ventricular function. Finally it should be recognized that studies to date have only evaluated NAPA's antiarrhythmic effect in one model for new drug evaluation, namely, the suppression of chronic asymptomatic or only moderately symptomatic ventricular arrhythmias. The compound needs further evaluation in patients with recurrent sustained ventricular tachycardia or ventricular fibrillation where antiarrhythmic action may possibly be independent of the suppression of isolated ventricular ectopic complexes.

Acknowledgment

We thank Inez Rodriguez and Betty Berdahl for performing ambulatory electrocardiographic analysis, Gail Yee and Sandra Harapat for assisting with the NAPA plasma concentration determinations and Glenda Rhodes and Cathy Cassady for secretarial assistance.

Mexiletine For Refractory-Ventricular Arrhythmias: Results Using Serial Electrophysiologic Testing

JOHN P. DiMARCO, MD, PhD
HASAN GARAN, MD*
JEREMY N. RUSKIN, MD, FACC

Boston, Massachusetts

Mexiletine was administered during serial drug testing to 35 patients with electrically inducible ventricular arrhythmias and to 6 with recurrent ventricular tachycardia that could not be induced or terminated by programmed cardiac stimulation. All patients had arrhythmias resistant to all conventionally available agents. Electrically induced arrhythmias were completely suppressed during mexiletine therapy in 13 patients. In 12 patients no antiarrhythmic regimen was completely suppressive and in 7 of these mexiletine favorably modified the response to programmed stimulation. In four of six patients with frequent episodes of spontaneous ventricular tachycardia that were not inducible by programmed cardiac stimulation, arrhythmia was controlled by mexiletine. The presence of complete arrhythmia suppression with mexiletine during acute testing accurately predicted long-term freedom from recurrent arrhythmia in 16 of 17 patients over a mean follow-up period of 12.6 ± 6 months. Severe adverse neurologic effects were noted early during mexiletine therapy in three patients, but no patient discharged on such therapy experienced major adverse effects. The study demonstrates that mexiletine can provide well tolerated effective prophylaxis against recurrent ventricular arrhythmias in a significant proportion of patients resistant to conventional drugs.

Mexiletine, 1-(2′,6′-dimethylphenoxy)-2-aminopropane, a primary amine structurally resembling lidocaine with anticonvulsant, antiarrhythmic and antifibrillatory properties, is currently under investigation in the United States for use in the treatment of ventricular arrhythmias. The drug has been demonstrated to be effective in preventing ventricular arrhythmias associated with acute myocardial infarction[1–3] as well as in a variety of other clinical settings.[4–7] These studies have reported an acceptable toxic to therapeutic ratio and pharmacokinetic properties that allow for convenient dosage regimens. The drug's potential role in the treatment of life-threatening ventricular arrhythmias has not been fully defined.

We and other groups[8–11] have found that patients with a history of either ventricular tachycardia or ventricular fibrillation frequently manifest reproducible ventricular arrhythmias in response to programmed electrical stimulation of the heart. The ability of a drug to suppress induction of tachycardia during such stimulation has been shown to predict antiarrhythmic efficacy.[8–11] In this report, we review our experience with the use of electrophysiologic techniques to assess the antiarrhythmic efficacy of mexiletine in 41 patients with life-threatening ventricular arrhythmias that were unresponsive to all conventionally available antiarrhythmic agents.

Methods

Study patients: We administered mexiletine to 41 patients with a history of recurrent ventricular tachycardia or ventricular fibrillation who had failed drug trials with all conventionally available antiarrhythmic agents. We defined a prior drug failure either as (1) an episode of symptomatic ventricular tachycardia or ventricular fibrillation occurring at a time when the plasma concentration of the antiarrhythmic agent was within the accepted therapeutic range, (2) an unacceptable toxic effect, or (3) the ability to induce a ventricular arrhythmia in the presence of adequate plasma concentration of the agent. All patients had been referred to the clinical electrophysiology laboratory of this hospital for comprehensive evaluation and prescription of antiarrhythmic therapy. The group consisted of 32 men and 9 women with a mean age of 56 years. Twenty-six patients had had recurrent ventricular tachycardia and 15 had had one or more episodes of ventricular fibrillation. All patients whose presenting arrhythmia had been associated with an acute myocardial infarction were excluded from this study. The primary cardiac diagnoses are listed in Table I.

Initial electrophysiologic studies: These studies were performed with the patient in a fasting, nonsedated state after informed consent had been given. Administration of antiarrhythmic drugs was discontinued at least 48 hours before the study in all but four patients. Digitalis, if required for heart failure or atrial fibrillation, and propranolol, if required for angina, were maintained at constant dosage throughout the period of study. Three quadripolar electrode catheters with a 1 cm interelectrode distance were inserted percutaneously through femoral and antecubital veins and positioned under fluoroscopic guidance at multiple intracardiac sites. Catheter positions in all patients included the lateral right atrium, the atrioventricular junction for recording electrical activity from the bundle of His, and the right ventricular apex. The distal pair of electrodes on each catheter was used for stimulation and the proximal pair for recording local electrograms. Intracardiac recordings were filtered at 30 to 500 hertz and displayed simultaneously with surface electrocardiographic leads I, II and V_1 on a multichannel oscilloscope (Electronics for Medicine VR-12). Data were stored on frequency modulated magnetic tape (A. R. Vetter Co.) and later retrieved on photographic paper at speeds of 100 to 200 mm/s.

Cardiac stimulation was performed with a programmable constant current stimulator (Medtronic 5325) that delivered rectangular pulses of 2 ms duration. All ventricular stimulation was carried out from the right ventricular apex at twice diastolic threshold. The following stimulation protocol was used:

1. Atrial pacing at rates from 100 to 300 beats/min.
2. Premature atrial stimulation during atrial pacing at one or more basic cycle lengths.
3. Ventricular pacing at rates from 60 to 150 beats/min for 30 seconds.
4. Premature ventricular stimulation with single (S_2) and double (S_2-S_3) extrastimuli during sinus rhythm and during fixed rate atrial and ventricular pacing after every eighth paced beat at multiple basic cycle lengths (S_1-S_1).
5. Rapid ventricular pacing at rates from 150 to 280 beats/min. Pacing bursts of 2 to 5 beats were delivered at progressively shorter cycle lengths until 1:1 ventricular capture could no longer be achieved, a ventricular arrhythmia occurred or a paced rate of 280 beats/min was reached.
6. If sustained ventricular tachycardia was initiated, bursts of rapid ventricular pacing at rates between 150 and 300 beats/min were applied in an attempt to terminate the arrhythmia. If ventricular fibrillation occurred or if ventricular tachycardia resulted in loss of consciousness, external electrical cardioversion was performed immediately.

Definitions: Sustained ventricular tachycardia was defined as ventricular tachycardia that persisted for at least 100 beats and required pacing, electrical cardioversion or drug administration for termination. Ventricular tachycardia was defined as nonsustained if it persisted for at least 5 beats and reverted spontaneously to the original rhythm within 100 beats. We considered repetitive ventricular responses significant only if they were 3 or 4 beats in length, could be reproducibly initiated, and were not due to His-Purkinje reentry. The stimulation protocol was carried to conclusion except in those patients who required external direct current countershock for termination of ventricular tachycardia or fibrillation.

Serial electrophysiologic testing during oral drug treatment: In the patients in whom programmed cardiac stimulation elicited a ventricular arrhythmia, an indwelling right ventricular apical pacing electrode was inserted percutaneously through a subclavian or antecubital vein and used to carry out serial electrophysiologic testing after 48 hours of therapy on each of a variety of oral drug regimens. The stimulation protocol employed was identical to that described except that atrial stimulation was not performed. Complete suppression of the ability to initiate a ventricular arrhythmia by programmed stimulation was the desired final end point (Fig. 1). If no antiarrhythmic regimen tested produced this result, the patient either underwent a cardiac surgical procedure, died in the hospital or was discharged on the antiarrhythmic regimen that had either maximally slowed or abbreviated the ventricular tachycardia or made it most difficult to induce during serial electrophysiologic testing. Therapy selected on the basis of these latter criteria was referred to as being partially suppressive.

Mexiletine protocol: Patients whose tachycardias were not inducible during programmed stimulation underwent a trial of mexiletine therapy during continuous ambulatory electrocardiographic monitoring for at least 4 consecutive 24 hour periods. Total abolition of all episodes of ventricular tachycardia with reappearance of the arrhythmia after discontinuation of mexiletine therapy was the criterion for complete suppression in this group.

Mexiletine was administered as a 400 mg loading dose followed by 400 to 1,200 mg daily in three or four divided doses. Because mexiletine plasma concentrations were not routinely available, the dosage in each patient was titrated upward until either a satisfactory response, a 1,200 mg daily dosage, or dose-related toxicity occurred. Serial electrophysiologic testing was performed as described. Except in two cases, combinations of other drugs with mexiletine were used only if the patient had failed to respond to each of the agents separately.

Results

Electrophysiologic observations: The essential clinical data and electrophysiologic observations for the 41 patients are presented in detail in Table I. Twenty of 26 patients with recurrent ventricular tachycardia and all 15 patients with prior ventricular fibrillation had electrically inducible ventricular arrhythmias. The mean rate of the induced tachycardias was 200 ± 37 (mean ± standard deviation) beats/min. Because of the reproducible modes of initiation and termination of these tachycardias, they were considered to be most probably due to reentry.[12,13] The remaining six patients, all of whom had had recurrent ventricular tachycardia,

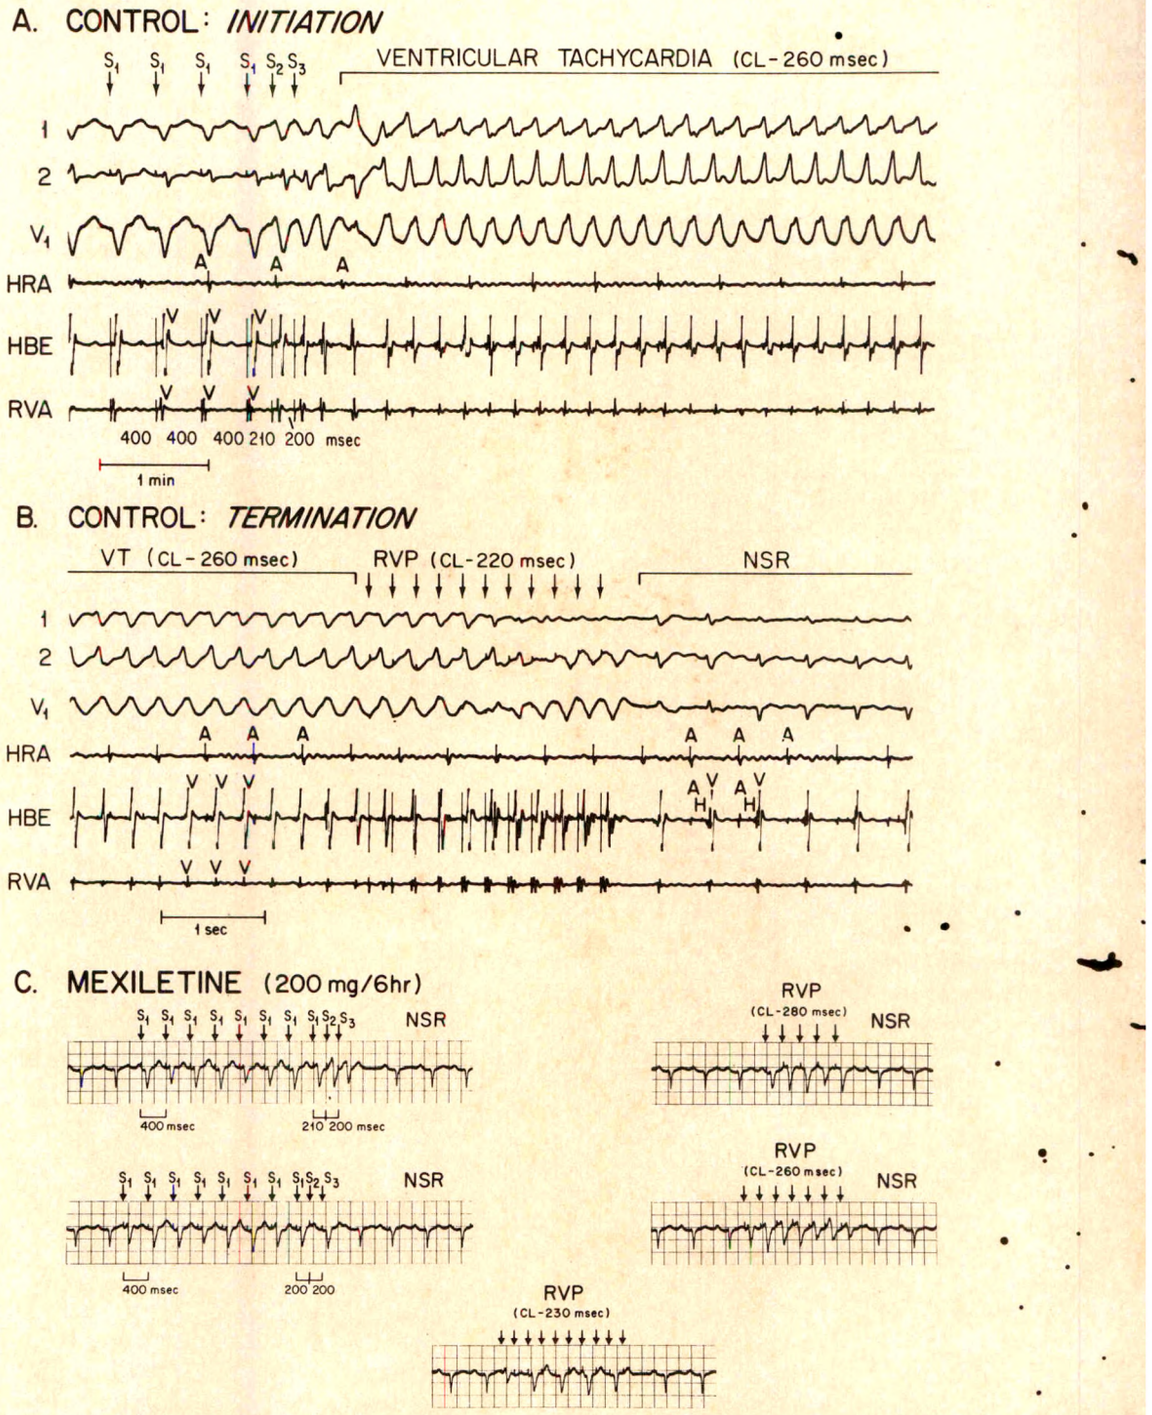

FIGURE 1. Case 11. Serial electrophysiologic testing in a patient with recurrent ventricular tachycardia. Panels **A** and **B** illustrate initiation and termination of ventricular tachycardia during control electrophysiologic studies while the patient was taking no antiarrhythmic drugs. In both panels, the tracings (**from top to bottom**) represent surface electrocardiographic leads I, II and V_1, a high right atrial electrocardiogram (HRA), a His bundle electrocardiogram (HBE) and a right ventricular apical electrocardiogram (RVA). In **A,** two sequential premature ventricular depolarizations (S_2 and S_3) delivered during fixed rate ventricular pacing (S_1 and S_1) result in the initiation of sustained ventricular tachycardia identical to that observed clinically. In **B,** the induced ventricular tachycardia (VT) is terminated by a burst of rapid ventricular pacing (RVP). **C** illustrates failure to initiate ventricular tachycardia in the same patient 48 hours after the initiation of therapy with oral mexiletine. All electrocardiograms in this panel represent lead II. The first tracing illustrates ventricular pacing and premature ventricular stimulation at cycle lengths and coupling intervals identical to those in panel **A** that reliably and reproducibly initiated ventricular tachycardia with the patient taking no drugs. The second electrocardiogram illustrates the effective refractory period of the right ventricular muscle encountered by the first premature ventricular stimulus (S_2). Premature ventricular stimulation with single (S_2) and double (S_2-S_3) stimuli over a full range of coupling intervals at multiple basic cycle lengths (S_1-S_1) failed to initiate ventricular tachycardia in the presence of mexiletine. The subsequent tracings (**on right**) illustrate bursts of rapid ventricular pacing at progressively shorter cycle lengths until only 2:1 capture of the ventricle occurs. Note failure of these bursts to initiate ventricular tachycardia. CL = cycle length; NSR = normal sinus rhythm.

Response to Mexiletine: Dependence on Rate of Induced Tachycardia (29 Patients*)

<185 beats/min (CL >325 ms, 155 ± 20 beats/min†)	
Complete suppression	0/8‡
Partial suppression	3/8
>185 beats/min (CL ≤325 ms, 230 ± 22 beats/min)	
Complete suppression	11/21‡
Partial suppression	4/21

* The four patients studied initially during treatment with another antiarrhythmic drug and the two patients with early neurologic toxicity are excluded. † Mean value ± standard deviation. ‡ p = 0.01 by Fisher's Exact Test.

had no electrically inducible tachycardias. The spontaneously occurring tachycardias in these patients exhibited a wide range of coupling intervals to the underlying rhythm at initiation, could be suppressed by supraventricular or ventricular overdrive with reappearance after cessation of the overdriving stimuli, and were not initiated by critically timed spontaneous premature beats. Because we have found the right ventricular apex to be the only suitable site for catheter placement during serial drug trials, we did not attempt stimulation at other ventricular sites. The electrophysiologic mechanism for the tachycardias in these six patients remains uncertain[12,13] and the arrhythmias are, henceforth, referred to as noninducible tachycardias.

Response to mexiletine: *Patients with inducible ventricular arrhythmias:* Thirteen of the 35 patients with electrically inducible ventricular arrhythmias manifested complete suppression of their ventricular tachycardia while receiving mexiletine either alone (9 patients) or in combination with a second agent that had previously been ineffective when used alone (4 patients). In 12 of the remaining 22 patients, inducible ventricular tachycardia could not be suppressed with any medical regimen attempted. In 7 of these 12 patients, a regimen consisting of mexiletine either alone or in combination with one or more other agents proved to be the best partially suppressive therapy. Thus, in 20 of 35 patients with electrically inducible ventricular arrhythmias, mexiletine constituted all or part of the final antiarrhythmic regimen.

Rapid ventricular tachycardias were more likely than slower tachycardias to be sensitive to mexiletine (Table II). Inducible tachycardias with rates below 185 beats/min (mean rate 155 ± 20 beats/min, n = 8) in the absence of antiarrhythmic drugs were not fully suppressed by mexiletine. In contrast, 52 percent (11 of 21) of the more rapid tachycardias (mean rate 230 ± 23 beats/min) were fully suppressed by mexiletine. In an additional 4 (19 percent) of 21 patients with rapid ventricular tachycardia, mexiletine, although not fully suppressive, provided the best partially suppressive therapy.

Patients with noninducible tachycardia: Mexiletine resulted in full control of spontaneously occurring arrhythmias in five of six patients with refractory noninducible ventricular tachycardia. However, in one patient, control could be maintained for only 4 days before an adverse reaction (see later) necessitated discontinuation of therapy.

Adverse reactions: Within 48 hours after the start of mexiletine therapy, episodes of spontaneous ventricular tachycardia occurred in four patients. Despite the absence of a clear causal relation, administration of mexiletine was discontinued in these patients and alternate modes of therapy were sought. Three patients exhibited severe neurologic side effects that required discontinuation of mexiletine within the first 5 days of treatment. These reactions were dysphagia and ataxia in one patient, and disabling tremor in two patients. About 50 percent of the patients treated reported minor adverse effects. Tremor at rest, epigastric distress, nausea and lightheadedness were the most common complaints with a peak incidence during the 2 hours after the first morning dose. These gastrointestinal and neurological side effects were usually eliminated by administering mexiletine with food. No evidence of deterioration in cardiac function due to mexiletine was observed in any patient.

Chronic mexiletine therapy: Twenty-four patients were maintained on chronic oral therapy with mexiletine (Table III). Fifteen of the 17 patients whose arrhythmias were suppressed during the acute phase of treatment remain free of recurrent arrhythmias at a mean follow-up period of 12.6 ± 6 months. One patient died after 12 months of mexiletine therapy as a result of refractory progressive heart failure. The other death occurred suddenly 15 months after hospital discharge and was presumably due to a ventricular arrhythmia. Two deaths have occurred among the seven patients in whom mexiletine therapy only partially suppressed the ability to electrically induce ventricular tachycardia. One other patient (Case 7) continues to experience tachycardias that he reliably terminates with a self-activated radiofrequency pacemaker.[14] The other four patients in this group remain free of arrhythmia at a mean follow-up time of 6.7 ± 4 months. No patient in this series experienced the onset of a major mexiletine-induced adverse effect during chronic therapy.

TABLE III

Chronic Mexiletine Therapy

Initial Response	Alive and Well (n)	Repeat VT/VF (SCD) (n)	Other Death	Follow-Up* (mo)
Complete suppression (17 patients)	15	1	1	12.6 ± 6
Partial suppression (7 patients)	5	2	—	6.7 ± 4

* Mean duration ± standard deviation.
SCD = sudden cardiac death; VF = ventricular fibrillation; VT = ventricular tachycardia.

Discussion

Antiarrhythmic effectiveness of mexiletine: In this study mexiletine proved to be useful in approximately 50 percent of patients with life-threatening ventricular arrhythmias that were refractory to treatment with all conventionally available antiarrhythmic agents. Previous investigators have reported satisfactory control of ventricular arrhythmias in from 40 to 90 percent of mexiletine-treated patients.[1–7] These authors used a reduction in the frequency and grade of spontaneous ventricular arrhythmia as the end point by which antiarrhythmic efficacy was assessed. However, most of these studies do not describe whether their patients had been responsive to other antiarrhythmic agents and, moreover, often only the acute suppression of ventricular arrhythmia is described without long-term follow-up. In our series, mexiletine was acutely effective in suppressing ventricular tachycardia in 42 percent (17 of 41) of patients. Furthermore, the results of acute drug testing with mexiletine were predictive of the absence of recurrent ventricular arrhythmias in a large majority (94 percent) of the cases at a mean follow-up time of 1 year. Because all the patients in our series were refractory to conventional antiarrhythmic drugs, the response to mexiletine of a less highly selected population of patients with recurrent ventricular arrhythmias might be considerably greater.

Mexiletine seemed to be more effective in suppressing rapid, rather than slow, inducible arrhythmias. When the results of therapy are analyzed with respect to the patients' presenting clinical arrhythmia, we found that 11 of the 15 patients with ventricular fibrillation, 14 of whom manifested rapid ventricular tachycardia at electrophysiologic study, were effectively treated with mexiletine whereas only 5 of 20 patients with recurrent ventricular tachycardia whose arrhythmias were electrically inducible were discharged on the drug. The mechanism responsible for this apparent rate-dependent sensitivity is unknown.

Adverse effects: Adverse effects appearing late after hospital discharge were not observed in the 24 patients maintained on long-term mexiletine therapy. This feature is an important advantage when long-term therapy is based on the results of intensive investigations during a brief in-hospital stay. During long-term therapy with procainamide, the late appearance of a lupus-like syndrome may frequently require discontinuation of a previously effective program. More rarely, patients initially responsive to quinidine may manifest late adverse effects or sensitivity that may similarly require a change in therapy. Aggravation of heart failure frequently complicates disopyramide therapy in patients with underlying left ventricular dysfunction.[15] In patients with prior life-threatening ventricular arrhythmias, such late complications frequently necessitate rehospitalization for additional antiarrhythmic drug testing. Although several of our patients were unable to tolerate standard doses of mexiletine, the major adverse effects were apparent within the first several days of therapy and all the patients discharged on mexiletine therapy were able to continue taking it throughout the follow-up period. In our experience with mexiletine in more than 80 patients, only 2 have required discontinuation of therapy because of adverse effects that appeared after the 1st week of therapy. When plasma levels become routinely available more precise individual dosage regimens can be designed that may lessen the incidence of dose-related toxicity.

Implications: Mexiletine appears to be a promising new antiarrhythmic agent that is capable of suppressing ventricular arrhythmias resistant to all conventionally available drugs in a significant proportion of patients. Electrically induced tachycardias with short cycle lengths as well as tachycardias not inducible by our techniques seem most likely to respond favorably. Therapy, once established, is well tolerated on a reasonable dosage schedule with minimal adverse effects and with no clinically discernible effect on left ventricular function.

Effects of intravenous ouabain were evaluated in 19 patients with an anomalous conduction pathway (14 with manifest and 5 with concealed preexcitation) utilizing intracardiac stimulation and recording. Anterograde conduction through the anomalous pathway was present in all 14 patients with manifest preexcitation at a maximal atrial paced rate of 140 to 250 beats/min (mean ± standard error of the mean 214 ± 7.2) before and at 150 to 240 beats/min (mean 206 ± 7.1) after ouabain (difference not significant [NS]). The anterograde effective refractory period of the anomalous pathway, measured at an equivalent atrial paced rate in 10 patients, was 250 to 450 ms (mean 309 ± 19.7) before and 260 to 450 ms (mean 300 ± 17.2) after ouabain (NS). Retrograde conduction through the anomalous pathway was possible at maximal ventricular paced rates (17 patients) of 160 to 250 beats/min (mean 222 ± 6.6) before and 190 to 250 beats/min (mean 221 ± 4.4) after ouabain (NS). Sustained atrioventricular (A-V) reentrant paroxysmal supraventricular tachycardia was inducible in all 19 patients before and in 17 patients (89 percent) after ouabain (tachycardia could not be induced in two patients because of increased A-V nodal refractoriness). The mean cycle length of tachycardia in the 17 patients was 320 ± 6.7 ms before and 340 ± 8.1 ms after ouabain ($p < 0.01$).

In conclusion, ouabain has no significant effect on either anterograde or retrograde anomalous pathway refractoriness. Although ouabain slightly increases the cycle length of tachycardia, it does not interfere with induction of tachycardia in most patients with preexcitation. Oral cardiac glycosides alone would appear to be of limited value in patients with preexcitation and recurrent supraventricular tachycardia.

Wellens and Durrer[1] reported the electrophysiologic effects of intravenously administered ouabain in six patients with the Wolff-Parkinson-White syndrome. They observed a mean decrease in anomalous pathway refractoriness of 28 ms after ouabain, and concluded that cardiac glycosides shorten anomalous pathway refractoriness. They also noted that ouabain interfered with induction of paroxysmal atrioventricular (A-V) reentrant supraventricular tachycardia in two of four patients with this arrhythmia. The effects of ouabain on retrograde conduction through the anomalous pathway were not specifically studied. In 10 patients with preexcitation who had atrial fibrillation induced by rapid atrial stimulation before and after administration of ouabain, Sellers et al.[2] found that ventricular rates were unchanged in one patient, decreased in six patients and increased in three. They related the increase in ventricular rate during atrial fibrillation (due to digitalis) to provocation of ventricular fibrillation.

In this study, we examined the effects of ouabain on electrophysiologic properties in 19 patients with either manifest or concealed preexcitation

and recurrent paroxysmal supraventricular tachycardia. We specifically evaluated the effects of this agent on anterograde and retrograde anomalous pathway properties, as well as on the ability to induce (from both atrium and ventricle) and sustain circus movement A-V reentrant tachycardias. Our results differ in some important respects from those previously reported.

Methods

Patient selection: The study group consisted of 19 patients, 15 male and 4 female, with anomalous A-V pathways undergoing electrophysiologic studies for documented recurrent paroxysmal supraventricular arrhythmia (17 with paroxysmal supraventricular tachycardia and 2 with paroxysmal atrial fibrillation). The subjects ages ranged from 12 to 64 years (mean ± standard error of the mean 43 ± 3.7).

Fourteen patients had manifest typical preexcitation (left-sided in nine and right-sided in five). Five patients had no anterograde preexcitation, but did have concealed left-sided anomalous A-V connections conducting in retrograde fashion.[3–5]

Electrophysiologic studies: The patients were studied in the postabsorptive nonsedated state after giving informed written consent. Antiarrhythmic therapy was discontinued at least 72 hours before the time of study. His bundle electrograms were recorded using previously described catheter techniques.[6] A hexapolar catheter, introduced through a right antecubital vein, was positioned at the right ventricular apex. The distal two electrodes of this catheter were utilized for right ventricular pacing; the proximal four electrodes were positioned against the right lateral atrial wall and were used for high and mid right atrial recording and stimulation. A third quadripolar electrode catheter, introduced through a left antecubital vein, was used for recording and stimulation from the coronary sinus. Recordings were obtained on a multichannel oscilloscopic photographic recorder (DR-20, Electronics for Medicine) at paper speeds of 100 and 200 mm/s. Simultaneous electrocardiographic leads I, II, III and V_1 were also recorded.

Incremental atrial pacing was performed in increments of 10 beats/min until one or more of the following was achieved: (1) a maximal atrial paced rate of 200 to 250 beats/min, (2) induction of paroxysmal supraventricular tachycardia, or (3) A-V nodal Wenckebach periodicity, or both (2) and (3). The minimal atrial paced rates at which anterograde block occurred in the anomalous pathway were noted. Anterograde refractory periods of the normal and anomalous pathways were determined during atrial paced drive using the extrastimulus technique as previously described.[7]

Anomalous pathway retrograde properties were studied utilizing response to incremental ventricular pacing and the ventricular extrastimulus technique.[8] Retrograde anomalous pathway conduction during supraventricular tachycardia was proved in all cases (both left- and right-sided anomalous connections) by one or more of the following criteria: (1) abnormal retrograde atrial activation sequence[8–10]; (2) ability to capture the atria during supraventricular tachycardia with critically timed ventricular extrastimuli delivered when the His bundle was refractory[11]; and (3) increase in ventriculoatrial (V-A) conduction time during supraventricular tachycardia with development of bundle branch block ipsilateral to the anomalous pathway.[12]

The presence of retrograde anomalous pathway conduction during incremental ventricular pacing was suggested by demonstration of one or more of the following criteria: (1) abnormal retrograde atrial activation sequence (early activation of atrium contiguous to the mid or lateral coronary sinus) detected in patients with a left-sided anomalous pathway (nine patients)[13]; (2) induction of supraventricular tachycardia with incremental ventricular pacing not related to a critical V-A interval, suggesting induction through block in the normal pathway (seven patients with a left-sided and two patients with a right-sided anomalous pathway)[14]; (3) fixed V-A conduction time during incremental ventricular pacing (17 patients)[9]; and (4) retrograde atrial activation sequence during incremental pacing identical to that observed during induced paroxysmal supraventricular tachycardia or A-V reentrant atrial echoes (17 patients).

The ventricles were paced at rates slightly above sinus rate and then in increments of 10 beats/min until one of the following was achieved: (1) a maximal paced rate of 200 to 250/min (depending on clinical status of the patient); (2) induction of paroxysmal supraventricular tachycardia; and (3) development of V-A block. The minimal ventricular paced rates at which retrograde block occurred in the anomalous pathway as suggested by either V-A block during anomalous pathway conduction or sudden prolongation of V-A conduction with concomitant change in atrial activation sequence were noted.

Ouabain administration: During anterograde and retrograde studies, the ability to induce and sustain paroxysmal supraventricular tachycardia as well as the cycle length of induced tachycardia were noted. All of these measurements were completed before administration of ouabain. After control measurements were made, 0.01 mg/kg of ouabain was administered intravenously.[1,15,16] Electrophysiologic studies were initiated 30 minutes later. No arrhythmias typically due to digitalis intoxication were noted. Refractory periods were measured at identical driven cycle lengths before and after ouabain (cycle length range 400 to 600 ms; mean 502 ± 18 ms).

Definitions: *The anterograde effective refractory period of the anomalous pathway* was defined as the longest atrial coupling interval at which block was achieved in the anomalous pathway (disappearance of delta wave). Anomalous pathway refractory periods were measured from the same site before and after administration of the drug. This site was close to the anomalous pathway location in most of the patients.[17]

The retrograde effective refractory period of the anomalous pathway was defined as the longest ventricular coupling interval ($V_1 - V_2$) at which V_2 failed to conduct to the atria through the anomalous pathway as suggested by either V-A block or a sudden increase and normalization of retrograde atrial activation sequence.[10] Ventricular pacing was performed from the right ventricular apex.

Paroxysmal supraventricular tachycardia was defined (for the purpose of this study) as A-V reentrant tachycardia utilizing the normal pathway for anterograde conduction and the anomalous pathway for retrograde conduction. No patient had sustained tachycardia utilizing the anomalous pathway in anterograde and the normal pathway in retrograde fashion. The tachycardia was defined as sustained if it lasted 30 seconds or more, necessitating termination with atrial or ventricular stimulation.

Results

Anomalous pathway anterograde and retrograde properties (Table I): Ability for intact (1:1) anomalous pathway anterograde conduction (a measurement related to anomalous pathway refractoriness) was demonstrated in all 14 patients with manifest preexcitation

AR = atrial rate; C = control period (before ouabain); CKB = concealed Kent bundle; KERP = effective refractory period of Kent bundle (anomalous pathway); Max AR = maximal atrial paced rate; Max VR = maximal ventricular paced rate; O = after ouabain; PSVT = paroxysmal supraventricular tachycardia; V-A = ventriculoatrial; VR = ventricular rate.

at maximal atrial paced rates of 140 to 250 beats/min (mean 214 ± 7.2) before and at 150 to 240 beats/min (mean 206 ± 7.1) after ouabain (NS). The anterograde effective refractory period of the anomalous pathway could be measured at identical cycle lengths in 10 of the 14 patients with manifest preexcitation before and after ouabain. In four patients, atrial refractoriness limited the measurement of the anomalous pathway anterograde refractory period. The anomalous pathway effective refractory period ranged from 250 to 450 ms (mean 309 ± 19.7) during the control period and from 260 to 450 ms (mean 300 ± 17.2) after administration of ouabain (NS) (Fig. 1).

Seventeen patients had intact retrograde anomalous pathway conduction at the maximal tested paced rates of 160 to 260 beats/min both before and after ouabain. The maximal paced heart rate for intact retrograde anomalous pathway conduction in these patients ranged from 160 to 260 beats/min (mean 222 ± 6.6) before and 190 to 250 beats/min (mean 221 ± 4.4) after administration of ouabain (NS). In two patients, retrograde anomalous pathway conduction was not tested with incremental ventricular pacing.

The retrograde effective refractory period of the anomalous pathway could be measured in 11 patients before and after administration of ouabain. The refractory periods in these patients ranged from 225 to 290 ms (mean 260 ± 7.4) before and from 225 to 310 ms (mean 261 ± 9.5) after ouabain (NS). Ventricular refractoriness precluded measurement of the retrograde anomalous pathway refractory period in the remaining eight patients. Ventricular refractory periods, measured in 16 patients, ranged from 160 to 270 ms (mean 231 ± 8.8 ms) before and from 160 to 270 ms (mean 228 ± 8.9) after administration of ouabain (NS).

Effect on paroxysmal supraventricular tachycardia (Table I): Sustained tachycardia could be induced in all 19 patients (100 percent) before administration of ouabain with use of one or more of the following techniques: (1) sudden cessation of rapid atrial

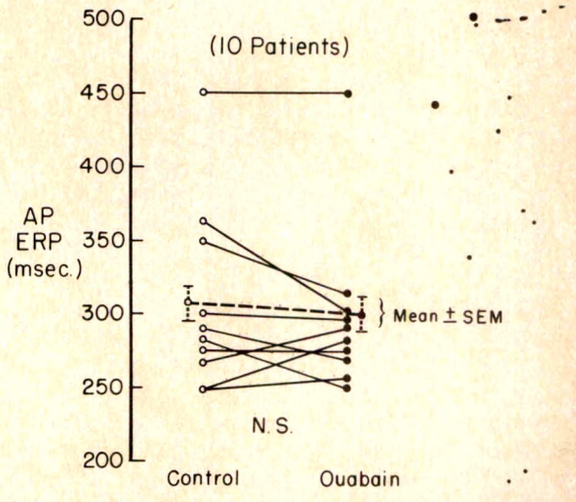

FIGURE 1. The effects of ouabain on anomalous pathway (AP) anterograde effective refractory periods (ERP) in 10 patients. Control values are shown on the **left,** post-ouabain values on the **right.** Mean values ± standard error of the mean (SEM). N.S. = difference not significant.

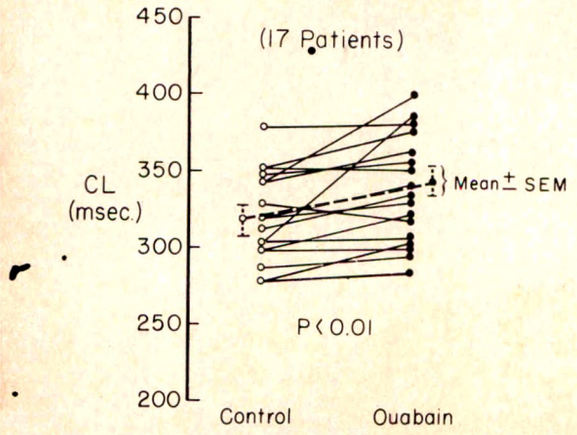

FIGURE 2. Effect of ouabain on the cycle length of induced paroxysmal supraventricular tachycardia before and after ouabain administration in 17 patients. CL = cycle length; P = probability; SEM = standard error of the mean.

pacing (16 patients); (2) atrial extrastimulus technique (9 patients); (3) cessation of rapid ventricular pacing (9 patients) and ventricular extrastimulus technique (6 patients). In all patients, induced paroxysmal supraventricular tachycardia was characterized by anterograde normal pathway conduction and retrograde anomalous pathway conduction.

In 17 (89 percent) of 19 patients, induction of sustained tachycardia was possible both before and after ouabain administration using identical stimulatory techniques. Tachycardia cycle lengths in these 17 patients ranged from 280 to 380 ms (mean 320 ± 6.7) before and from 290 to 400 ms (mean 340 ± 8.1) after ouabain ($p < 0.01$). This change in tachycardia cycle length was equivalent to a decrease in the rate of paroxysmal supraventricular tachycardia of 14 beats/min (heart rate 190 beats/min before and 176 beats/min after ouabain). The longer cycle lengths after ouabain reflected an increase in A-V nodal conduction (A-H interval) during paroxysmal supraventricular tachycardia, without change in H-A intervals (Fig. 2). In 2 (10 percent) of the 19 patients, the ability to induce paroxysmal supraventricular tachycardia was lost after ouabain administration. This loss reflected an increase in A-V nodal refractoriness that prevented repetitive sequential anterograde normal pathway conduction.

Discussion

Mechanism of paroxysmal supraventricular tachycardia and atrial fibrillation in Wolff-Parkinson-White syndrome: Current evidence suggests that patients with the Wolff-Parkinson-White syndrome have an extranodal anomalous pathway that bypasses the normal A-V nodal conduction system.[9–13,17–19] These patients are prone to A-V reentrant paroxysmal supraventricular tachycardia. Such tachycardia in patients with the Wolff-Parkinson-White syndrome is most commonly characterized by narrow QRS complexes, and reflects a circus movement with anterograde conduction in the normal A-V nodal pathway and retrograde conduction in an anomalous extranodal pathway. Induction of paroxysmal supraventricular tachycardia can be achieved either from the atrium, with atrial impulses that block in the anomalous pathway and conduct in anterograde fashion through the normal pathway, or from the ventricle, with ventricular impulses that block in the normal pathway and conduct in retrograde manner through the anomalous pathway.[20]

Patients with preexcitation are also susceptible to atrial fibrillation.[21–25] The mechanism of atrial fibrillation in patients with the Wolff-Parkinson-White syndrome is not thoroughly understood. In some patients, A-V reentrant paroxysmal supraventricular tachycardia and atrial fibrillation appear to be related, as evidenced by the observation of paroxysmal supraventricular tachycardia spontaneously degenerating into atrial fibrillation.[22–24] In other patients, associated organic heart disease, sinoatrial dysfunction or other as yet unmeasured atrial properties may play a role in the occurrence of paroxysmal atrial fibrillation. In patients with preexcitation and paroxysmal atrial fibrillation, the ventricular rate is determined by anterograde anomalous pathway refractoriness.[21–25]

Effects of digitalis in preexcitation syndrome: The use of digitalis in patients with preexcitation could have potentially beneficial as well as deleterious effects on arrhythmias complicating preexcitation.[1,2] If digitalis increased A-V nodal refractoriness to a critical degree, it might interfere with ability to sustain A-V reentrant tachycardia, and result in cure of recurrent paroxysmal supraventricular tachycardia. In patients with atrial fibrillation complicating preexcitation, if digitalis decreased anterograde anomalous pathway refractoriness, it would result in increased ventricular rates during this arrhythmia.[21] Independent of its effect on anomalous pathway refractoriness, digitalis (particularly at toxic levels) could make the ventricles more prone to ventricular fibrillation.

Electrophysiologic techniques have provided some insight into the potential values and hazards of digitalis in patients with the Wolff-Parkinson-White syndrome.[1,2] Wellens and Durrer[1] studied the effects of intravenous ouabain in six patients with preexcitation (type A in four and type B in two), noting that this agent shortened anomalous pathway anterograde refractoriness in all. Anomalous pathway effective refractory period ranged from 230 to 360 ms (mean 305) before and from 210 to 350 ms (mean 277) after ouabain. Statistical analysis of these results was not reported. The decrease in anomalous pathway refractoriness demonstrated by Wellens and Durrer[1] suggested that digitalis would probably increase ventricular rates in patients with atrial fibrillation complicating preexcitation. Sellers et al.[2] studied this question more directly, by examining the effect of intravenous digoxin on atrial fibrillation induced by atrial stimulation in 10 patients with preexcitation. In contrast to what might have been expected, they noted a mean increase in ventricular cycle length of 69 ms during atrial fibrillation (from 379 ms

before to 448 ms after digoxin). Specifically, they noted slowing of ventricular rate in six patients, no change in ventricular rate in one patient, and increase in ventricular rate in three patients. They suggested that the decrease of ventricular cycle length seen in some patients (increase in ventricular rates) might relate to provocation of ventricular fibrillation.

The question arises whether our results can be reconciled with those of the preceding reports. In summary, we demonstrated no significant effect of ouabain on either anterograde or retrograde anomalous pathway refractoriness, utilizing the atrial extrastimulus technique, atrial incremental pacing, ventricular extrastimulus technique and incremental ventricular pacing. We noted a loss of ability to induce sustained paroxysmal supraventricular tachycardia in only 2 (10 percent) of 19 patients after ouabain. We did note slight (but significant) slowing of cycle length of induced paroxysmal tachycardia in the remaining 17 patients after ouabain. We did not attempt induction of atrial fibrillation before and after ouabain.

Our own statistical analysis of the previously reported 16 cases,[1,2] utilizing the unpaired *t* test, revealed that ouabain had no significant effect on anomalous pathway refractoriness (Wellens and Durrer[1]) and no significant effect on ventricular rates or shortest observed R-R interval during atrial fibrillation after digoxin (Sellers et al.[2]). Their results would thus seem to be entirely consistent with our demonstration of insignificant effect of ouabain on anterograde anomalous pathway refractoriness. The previously observed changes in some patients of either anomalous pathway refractory periods or ventricular rates during atrial fibrillation following digitalis may in fact be biologic variability of the measured variables, as opposed to a true pharmacologic effect of cardiac glycosides on anomalous pathway properties.

Our observation of lack of effect of ouabain on retrograde anomalous pathway refractoriness is certainly consistent with the lack of effect on anterograde refractoriness. This particular variable of anomalous pathway function has not been systematically studied previously. The ability for retrograde anomalous pathway conduction would relate to ability for sustained circus movement tachycardias in patients with preexcitation. If ouabain were to interfere with induction of paroxysmal tachycardia in preexcitation, it would have to be by affecting the A-V node. Ouabain is known to increase A-V nodal refractoriness.[26] In our study, this increase in A-V nodal refractoriness after ouabain was insufficient to prevent induction of sustained A-V reentrant paroxysmal tachycardia in most of our patients. However, an increase in A-V nodal conduction delay due to ouabain, as manifested by an increase in A-H interval during paroxysmal supraventricular tachycardia, did increase the cycle length of induced tachycardia. Why Wellens and Durrer[1] found ouabain effective in preventing induction of paroxysmal tachycardia in 50 percent of their cases (2 of 4), whereas we found a similar effect in only 10 percent (2 of 19) of patients, may relate to methodology. Wellens and Durrer[1] utilized only atrial extrastimulus induction of tachycardia, whereas we utilized tachycardia induction from either atrium or ventricle. Our approach would seem more reasonable, since there are no data suggesting that only one mode of stimulation is the appropriate one for quantifying drug effects on ability to induce sustained circus movement tachycardias.

Clinical implications: Acute intravenous administration of ouabain in patients with preexcitation had no significant effect on anomalous pathway anterograde or retrograde refractoriness. Ouabain prevented induction of circus movement paroxysmal supraventricular tachycardia in only a limited number of cases. However, it significantly increased the cycle length of induced tachycardia by depressing A-V nodal conduction.

Recent reports utilizing long-term electrophysiologic studies in patients with recurrent paroxysmal tachycardia suggest that response to acute intravenous drug administration predicts future response to oral administration of the same drug.[27] The results of our study with intravenous ouabain suggest that in patients with preexcitation (both manifest and concealed), oral glycosides alone would be of limited value in preventing attacks of paroxysmal supraventricular tachycardia. The increase in cycle length of tachycardia produced by this agent would appear to be of limited clinical value.

In patients with paroxysmal atrial fibrillation complicating preexcitation with a short anomalous pathway refractory period, digitalis is generally contraindicated. The lack of significant effect of this agent on anomalous pathway refractoriness, coupled with possible increase in ventricular vulnerability to ventricular fibrillation (particularly if digitalis were used in large amounts), suggests that this agent would be dangerous. There are no data concerning the potential risk of cardiac glycosides in patients with preexcitation who have not had paroxysmal atrial fibrillation.

THE TRENDSETTER™ — The top-of-the-line scanner for integrated ECG, blood pressure and pacemaker evaluation, together with comprehensive alphanumeric/graphic summaries.

VIS-U-SCAN™ — The high-speed system that puts 24 hours of ECG in your hands in three minutes flat without missing a beat.

SMART SCANNERS, SMART VALUES

There's a Del Mar Avionics ECG scanner that satisfies your most exacting requirements — in the hospital or in your office. And a worldwide network of servi centers assures fast, professional response when you need it, where you need it.

An outstanding Education and Training staff rounds out our commitment to excellence. Training courses extend the skills and knowledge of your staff in the app cation of ECG principles to Holter System data analysis.

Our full line of smart scanners coupled with the extra services only a leader can provide, makes your investment in a Del Mar Avionics system a smart move. C your local representative today.

MODEL 653/656A — The compact Holter scanning system handles the workload right in your office. Two channels of data with memory-scope display make it fast, flexible and easy-to-use.

*THE EVALUATOR,™ **NEW!** — The middle-of-the-line Holter ECG scanner — microprocessor-controlled, features "smart" arrhythmia analyzer.*

REGULATING
THE
ARRHYTHMIC
HEART...

INDERAL®
(PROPRANOLOL HCl)
BETTER SOONER THAN LATER

ALONE Excessive exertions. Emotional upheavals. Anxieties. Stress. Catecholamines rise—atrial pacemakers overrespond. And the ECG reads PAT. Or persistent sinus tachycardia. Or persistent atrial extrasystoles. Consider INDERAL (propranolol HCl) alone. When conventional measures fail, a low 10 to 30 mg dose, given t.i.d. or q.i.d., will block cardiac beta-receptors from excessive catecholamine stimulation. Suppress ectopic pacemakers. And permit resumption of normal sinus rhythm. Even when normal sinus rhythm has not been restored, INDERAL slows conduction in the AV node and prolongs its refractory time. Slowed AV conduction will often block reentry circuits, to help restore sinus rhythm.

WITH The ECG reads atrial flutter. Or atrial fibrillation. You have digitalized your patient, but the arrhythmia is not yet controlled. Consider adding INDERAL (propranolol HCl). Combined with digitalis, it obviates increasing digitalis dosage to toxic levels—while slowing the ventricular rate sufficiently to achieve control. INDERAL also complements the action of other agents. Combined with quinidine, it allows lower doses of quinidine—reducing the need for toxic levels. And often, with INDERAL added, atrial arrhythmias respond when no single agent works alone.

INSTEAD The arrhythmia is induced by an antiarrhythmic drug such as digitalis or quinidine. Persists after discontinuance of the drug and correction of electrolyte imbalance. Consider INDERAL instead. Often the drug of choice, except in the presence of serious congestive heart failure. Often, too, INDERAL (propranolol HCl) abolishes supraventricular arrhythmias when either digitalis or quinidine has failed.

With proper patient selection—in the absence of contraindications such as bradycardia, greater than first degree heart block, asthma, and congestive heart failure unless failure is secondary to tachyarrhythmias treatable with INDERAL—serious cardiovascular and respiratory side effects are seldom encountered.* Rely on it: INDERAL. Alone. With. Or Instead.

*Please turn the page for brief summary of prescribing information on contraindications, adverse reactions, and warnings, including avoidance of abrupt withdrawal.

A PRIME CONSIDERATION FOR SUPRAVENTRICULAR ARRHYTHMIAS

INDERAL®
(PROPRANOLOL HCl)
10mg and 20mg tablets

Ayerst®

BRIEF SUMMARY
(FOR FULL PRESCRIBING INFORMATION, SEE PACKAGE CIRCULAR)
Inderal® BRAND OF propranolol hydrochloride **A beta-adrenergic blocking agent**

BEFORE USING INDERAL (PROPRANOLOL HYDROCHLORIDE), THE PHYSICIAN SHOULD BE THOROUGHLY FAMILIAR WITH THE BASIC CONCEPT OF ADRENERGIC RECEPTORS (ALPHA AND BETA), AND THE PHARMACOLOGY OF THIS DRUG.

ACTIONS: INDERAL is a beta-adrenergic receptor blocking drug, possessing no other autonomic nervous system activity. It specifically competes with beta-adrenergic receptor stimulating agents for available beta receptor sites. When access to beta receptor sites is blocked by INDERAL, the chronotropic, inotropic, and vasodilator responses to beta-adrenergic stimulation are decreased proportionately.

Propranolol is almost completely absorbed from the gastrointestinal tract, but a portion is immediately bound by the liver. Peak effect occurs in one to one and one-half hours. The biologic half-life is approximately two to three hours. Propranolol is not significantly dialyzable. There is no simple correlation between dose or plasma level and therapeutic effect, and the dose-sensitivity range as observed in clinical practice is wide. The principal reason for this is that sympathetic tone varies widely between individuals. Since there is no reliable test to estimate sympathetic tone or to determine whether total beta blockade has been achieved, proper dosage requires titration.

Beta receptor blockade is useful in conditions in which, because of pathologic or functional changes, sympathetic activity is excessive or inappropriate and detrimental to the patient. But there are also situations in which sympathetic stimulation is vital. For example, in patients with severely damaged hearts, adequate ventricular function is maintained by virtue of sympathetic drive which should be preserved. In the presence of AV block, beta blockade may prevent the necessary facilitating effect of sympathetic activity on conduction. Beta blockade results in bronchial constriction by interfering with adrenergic bronchodilator activity which should be preserved in patients subject to bronchospasm.

The proper objective of beta blockade therapy is to decrease adverse sympathetic stimulation but not to the degree that may impair necessary sympathetic support.

Propranolol exerts its antiarrhythmic effects in concentrations associated with beta-adrenergic blockade and this appears to be its principal antiarrhythmic mechanism of action. The membrane effect also plays a role, particularly, some authorities believe, in digitalis-induced arrhythmias.

Beta-adrenergic blockade is of unique importance in the management of arrhythmias due to increased levels of circulating catecholamines or enhanced sensitivity of the heart to catecholamines (arrhythmias associated with pheochromocytoma, thyrotoxicosis, exercise).

In dosages greater than required for beta blockade, INDERAL also exerts a quinidine-like or anesthetic-like membrane action which affects the cardiac action potential and depresses cardiac function.

Propranolol may reduce the oxygen requirement of the heart at any given level of effort by blocking catecholamine-induced increases in heart rate, systolic blood pressure, and the velocity and extent of myocardial contraction. On the other hand, propranolol may increase oxygen requirements by increasing left ventricular fiber length, end diastolic pressure, and systolic ejection period.

If the net physiologic effect of beta-adrenergic blockade in angina is advantageous, it would be expected to manifest itself during exercise by delayed onset of pain due to decreased oxygen requirement.

INDICATIONS: Cardiac Arrhythmias: *1.) Supraventricular arrhythmias:* a) Paroxysmal atrial tachycardias, particularly those arrhythmias induced by catecholamines or digitalis or associated with the Wolff-Parkinson-White syndrome. (See W-P-W under WARNINGS.) b) Persistent sinus tachycardia which is noncompensatory and impairs the well-being of the patient. c) Tachycardias and arrhythmias due to thyrotoxicosis when causing distress or increased hazard and when immediate effect is necessary as adjunctive, short term (2-4 weeks) therapy. May be used with, but not in place of, specific therapy. (See Thyrotoxicosis under WARNINGS.) d) Persistent atrial extrasystoles which impair the well-being of the patient and do not respond to conventional measures. e) Atrial flutter and fibrillation when ventricular rate cannot be controlled by digitalis alone, or when digitalis is contraindicated.

2.) Ventricular tachycardias: Ventricular arrhythmias do not respond to propranolol as predictably as do the supraventricular arrhythmias. a) Ventricular tachycardias: With the exception of those induced by catecholamines or digitalis, INDERAL is not the drug of first choice. In critical situations when cardioversion technics or other drugs are not indicated or are not effective, INDERAL may be considered. If, after consideration of the risks involved, INDERAL is used, it should be given intravenously in low dosage and very slowly. (See DOSAGE AND ADMINISTRATION.) *Care in the administration of* INDERAL *with constant electrocardiographic monitoring is essential as the failing heart requires some sympathetic drive for maintenance of myocardial tone.* b) Persistent premature ventricular extrasystoles which do not respond to conventional measures and impair the well-being of the patient.

3.) Tachyarrhythmias of digitalis intoxication: If digitalis-induced tachyarrhythmias persist following discontinuance of digitalis and correction of electrolyte abnormalities, they are usually reversible with *oral* INDERAL. Severe bradycardia may occur. (See OVERDOSAGE OR EXAGGERATED RESPONSE.)

Intravenous propranolol hydrochloride is reserved for life-threatening arrhythmias. Temporary maintenance with oral therapy may be indicated. (See DOSAGE AND ADMINISTRATION.)

4.) Resistant tachyarrhythmias due to excessive catecholamine action during anesthesia. Tachyarrhythmias due to excessive catecholamine action during anesthesia may sometimes arise because of release of endogenous catecholamines or administration of catecholamines. When usual measures fail in such arrhythmias, INDERAL may be given intravenously to abolish them. All general inhalation anesthetics produce some degree of myocardial depression. Therefore, when INDERAL is used to treat arrhythmias during anesthesia, it should be used with extreme caution and constant ECG and central venous pressure monitoring. (See WARNINGS.)

Hypertrophic Subaortic Stenosis: INDERAL is useful in the management of hypertrophic subaortic stenosis, especially for treatment of exertional or other stress-induced angina, palpitations, and syncope. INDERAL also improves exercise performance. The effectiveness of INDERAL in this disease appears to be due to a reduction of the elevated outflow pressure gradient which is exacerbated by beta receptor stimulation. Clinical improvement may be temporary.

Pheochromocytoma: After primary treatment with an alpha-adrenergic blocking agent has been instituted, INDERAL may be useful as *adjunctive* therapy if the control of tachycardia becomes necessary before or during surgery.

It is hazardous to use INDERAL unless alpha-adrenergic blocking drugs are already in use, since this would predispose to serious blood pressure elevation. Blocking only the peripheral dilator (beta) action of epinephrine leaves its constrictor (alpha) action unopposed.

In the event of hemorrhage or shock, there is a disadvantage in having both beta and alpha blockade since the combination prevents the increase in heart rate and peripheral vasoconstriction needed to maintain blood pressure.

With inoperable or metastatic pheochromocytoma, INDERAL may be useful as an adjunct to the management of symptoms due to excessive beta receptor stimulation.

CONTRAINDICATIONS: INDERAL is contraindicated in: 1) bronchial asthma; 2) allergic rhinitis during the pollen season; 3) sinus bradycardia and greater than first degree block; 4) cardiogenic shock; 5) right ventricular failure secondary to pulmonary hypertension; 6) congestive heart failure (see WARNINGS) unless the failure is secondary to a tachyarrhythmia treatable with INDERAL; 7) in patients on adrenergic-augmenting psychotropic drugs (including MAO inhibitors), and during the two week withdrawal period from such drugs.

WARNINGS: CARDIAC FAILURE: Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and inhibition with beta-blockade always carries the potential hazard of further depressing myocardial contractility and precipitating cardiac failure. INDERAL acts selectively without abolishing the inotropic action of digitalis on the heart muscle (i.e., that of supporting the strength of myocardial contractions). In patients already receiving digitalis, the positive inotropic action of digitalis may be reduced by INDERAL's negative inotropic effect. The effects of INDERAL and digitalis are additive in depressing AV conduction.

IN PATIENTS WITHOUT A HISTORY OF CARDIAC FAILURE, continued depression of the myocardium over a period of time can, in some cases, lead to cardiac failure. In rare instances, this has been observed during INDERAL therapy. Therefore, at the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or given a diuretic, and the response observed closely: a) if cardiac failure continues, despite adequate digitalization and diuretic therapy, INDERAL therapy should be immediately withdrawn; b) if tachyarrhythmia is being controlled, patients should be maintained on combined therapy and the patient closely followed until threat of cardiac failure is over.

IN PATIENTS WITH ANGINA PECTORIS, there have been reports of exacerbation of angina and, in some cases, myocardial infarction, following *abrupt* discontinuation of INDERAL therapy. Therefore, when discontinuance of INDERAL is planned the dosage should be gradually reduced and the patient carefully monitored. In addition, when INDERAL is prescribed for angina pectoris, the patient should be cautioned against interruption or cessation of therapy without the physician's advice. If INDERAL therapy is interrupted and exacerbation of angina occurs, it usually is advisable to reinstitute INDERAL therapy and take other measures appropriate for the management of unstable angina pectoris. Since coronary artery disease may be unrecognized, it may be prudent to follow the above advice in patients considered at risk of having occult atherosclerotic heart disease, who are given propranolol for other indications.

IN PATIENTS WITH THYROTOXICOSIS, possible deleterious effects from long term use not been adequately appraised. Special consideration should be given to propranolol's p tial for aggravating congestive heart failure. Propranolol may mask the clinical signs of de ing or continuing hyperthyroidism or complications and give a false impression of improv Therefore, abrupt withdrawal of propranolol may be followed by an exacerbation of sympt of hyperthyroidism, including thyroid storm. This is another reason for withdrawing propra slowly. Propranolol does not distort thyroid function tests.

IN PATIENTS WITH WOLFF-PARKINSON-WHITE SYNDROME, several cases have beer ported in which, after propranolol, the tachycardia was replaced by a severe bradycardia quiring a demand pacemaker. In one case this resulted after an initial dose of 5 mg propra

IN PATIENTS DURING ANESTHESIA with agents that require catecholamine release for tenance of adequate cardiac function, beta blockade will impair the desired inotropic effe Therefore, INDERAL should be titrated carefully when administered for arrhythmias occur during anesthesia.

IN PATIENTS UNDERGOING MAJOR SURGERY, beta blockade impairs the ability of the heart to respond to reflex stimuli. For this reason, with the exception of pheochromocytom INDERAL should be withdrawn 48 hours prior to surgery, at which time all chemical and ph siologic effects are gone according to available evidence. However, in case of emergency gery, since INDERAL is a competitive inhibitor of beta receptor agonists, its effects can be versed by administration of such agents, *e.g.*, isoproterenol or levarterenol. However, suc tients may be subject to protracted severe hypotension. Difficulty in restarting and maintai the heart beat has also been reported.

IN PATIENTS PRONE TO NONALLERGIC BRONCHOSPASM (*e.g.*, CHRONIC BRONCH EMPHYSEMA), INDERAL should be administered with caution since it may block broncho tion produced by endogenous and exogenous catecholamine stimulation of beta recepto

DIABETICS AND PATIENTS SUBJECT TO HYPOGLYCEMIA: Because of its beta-adrene blocking activity, INDERAL may prevent the appearance of premonitory signs and sympto (pulse rate and pressure changes) of acute hypoglycemia. This is especially important to k in mind in patients with labile diabetes. Hypoglycemic attacks may be accompanied by a cipitous elevation of blood pressure.

USE IN PREGNANCY: The safe use of INDERAL in human pregnancy has not been es-tablished. Use of any drug in pregnancy or women of childbearing potential requires that t possible risk to mother and/or fetus be weighed against the expected therapeutic benefit. bryotoxic effects have been seen in animal studies at doses about 10 times the maximum r ommended human dose.

PRECAUTIONS: Patients receiving catecholamine depleting drugs such as reserpine sho be closely observed if INDERAL is administered. The added catecholamine blocking actio this drug may then produce an excessive reduction of the resting sympathetic nervous act Occasionally, the pharmacologic activity of INDERAL may produce hypotension and/or m bradycardia resulting in vertigo, syncopal attacks, or orthostatic hypotension.

As with any new drug given over prolonged periods, laboratory parameters should be o served at regular intervals. The drug should be used with caution in patients with impaired or hepatic function.

ADVERSE REACTIONS: *Cardiovascular:* bradycardia; congestive heart failure; intensific of AV block; hypotension; paresthesia of hands; arterial insufficiency, usually of the Raynau type; thrombocytopenic purpura

Central Nervous System: lightheadedness; mental depression manifested by insomnia, tude, weakness, fatigue; reversible mental depression progressing to catatonia; visual dis bances; hallucinations; an acute reversible syndrome characterized by disorientation for t and place, short term memory loss, emotional lability, slightly clouded sensorium, and de-creased performance on neuropsychometrics

Gastrointestinal: nausea, vomiting, epigastric distress, abdominal cramping, diarrhea, c stipation, mesenteric arterial thrombosis, ischemic colitis

Allergic: pharyngitis and agranulocytosis, erythematous rash, fever combined with achi and sore throat, laryngospasm and respiratory distress

Respiratory: bronchospasm

Hematologic: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpu

Miscellaneous: reversible alopecia. Oculomucocutaneous reactions involving the skin, s rous membranes and conjunctivae reported for a beta blocker (practolol) have not been c clusively associated with propranolol.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe hea ease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

DOSAGE AND ADMINISTRATION: The dosage range for INDERAL is different for eac indication.

ORAL

ARRHYTHMIAS—10-30 mg three or four times daily, before meals and at bedtime.

HYPERTROPHIC SUBAORTIC STENOSIS—20-40 mg three or four times daily, before m and at bedtime.

PHEOCHROMOCYTOMA—*Preoperatively*—60 mg daily in divided doses for three days to surgery, concomitantly with an alpha-adrenergic blocking agent.—*Management of inop ble tumor*—30 mg daily in divided doses.

PEDIATRIC DOSAGE At this time the data on the use of the drug in this age group are to ited to permit adequate directions for use.

INTRAVENOUS Intravenous administration is reserved for life-threatening arrhythmias o those occurring under anesthesia. The usual dose is from 1 to 3 mg administered under ca monitoring, *e.g.* electrocardiographic, central venous pressure. The rate of administration should not exceed 1 mg (1 ml) per minute to diminish the possibility of lowering blood press and causing cardiac standstill. Sufficient time should be allowed for the drug to reach the s action even when a slow circulation is present. If necessary, a second dose may be given a two minutes. Thereafter, additional drug should not be given in less than four hours. Additio INDERAL should not be given when the desired alteration in rate and/or rhythm is achieve

Transference to oral therapy should be made as soon as possible.

The intravenous administration of INDERAL has not been evaluated adequately in the m agement of hypertensive emergencies.

OVERDOSAGE OR EXAGGERATED RESPONSE: IN THE EVENT OF OVERDOSAGE OR EXAGGERATED RESPONSE, THE FOLLOWING MEASURES SHOULD BE EMPLOYED:

BRADYCARDIA—ADMINISTER ATROPINE (0.25 to 1.0 mg): IF THERE IS NO RESPONSE VAGAL BLOCKADE, ADMINISTER ISOPROTERENOL CAUTIOUSLY.

CARDIAC FAILURE—DIGITALIZATION AND DIURETICS.

HYPOTENSION—VASOPRESSORS,*e.g.* LEVARTERENOL OR EPINEPHRINE (THERE IS DENCE THAT EPINEPHRINE IS THE DRUG OF CHOICE.)

BRONCHOSPASM—ADMINISTER ISOPROTERENOL AND AMINOPHYLLINE.

HOW SUPPLIED: INDERAL (propranolol hydrochloride)

TABLETS: *No. 461*—Each scored tablet contains 10 mg of propranolol hydrochloride, in bo of 100 and 1,000. Also in unit dose package of 100. *No. 462*—Each scored tablet contains 20 mg of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package 100. *No. 464*—Each scored tablet contains 40 mg of propranolol hydrochloride, in bottles 100 and 1,000. Also in unit dose package of 100. *No. 468*—Each scored tablet contains 80 of propranolol hydrochloride, in bottles of 100 and 1,000. Also in unit dose package of 100.

INJECTABLE: *No. 3265*—Each ml contains 1 mg of propranolol hydrochloride in Water for I tion. The pH is adjusted with citric acid. Supplied as: 1 ml ampuls in boxes of 10.

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC

Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, Univer. of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama

Henry N. Neufeld, MD, FACC

Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief Heart Institute, Chaim Sheba Medical Center, Tel-Hashomer, University of Tel Aviv—Sackler School of Medicine

$33.00 SEPTEMBER 1978, 288 PAGES, 110 ILLUS, 1,000 REF.

Every Cardiologist, Internist, Pediatrician, Surgeon — Indeed, *Every Physician* — Should Have a Good Basic Knowledge of The Pre-excitation Syndrome. Here Are Just a Few Reasons Why This is so Essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

The 13 Chapters Are a Comprehensive Summary

1. General Considerations
2. The Electrocardiogram in the Pre-excitation Syndrome: Complexes and Configurations
3. The Electrocardiogram in the Pre-excitation Syndrome: Disturbances of Rate and Rhythm
4. Pathology
5. Noninvasive Methods of Investigation
6. Invasive Methods of Investigation
7. Prognosis
8. Treatment
9. Problems of Diagnosis — Some Illustrative Cases
10. Summary of Findings and Theories of Pre-excitation Syndrome
11. Concept of Interacting Structural and Functional Factors
12. Explanation of Some Phenomena of the Pre-excitation Syndrome by the Proposed Concept
13. Various QRS Patterns in the Different Forms of Pre-excitation

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals

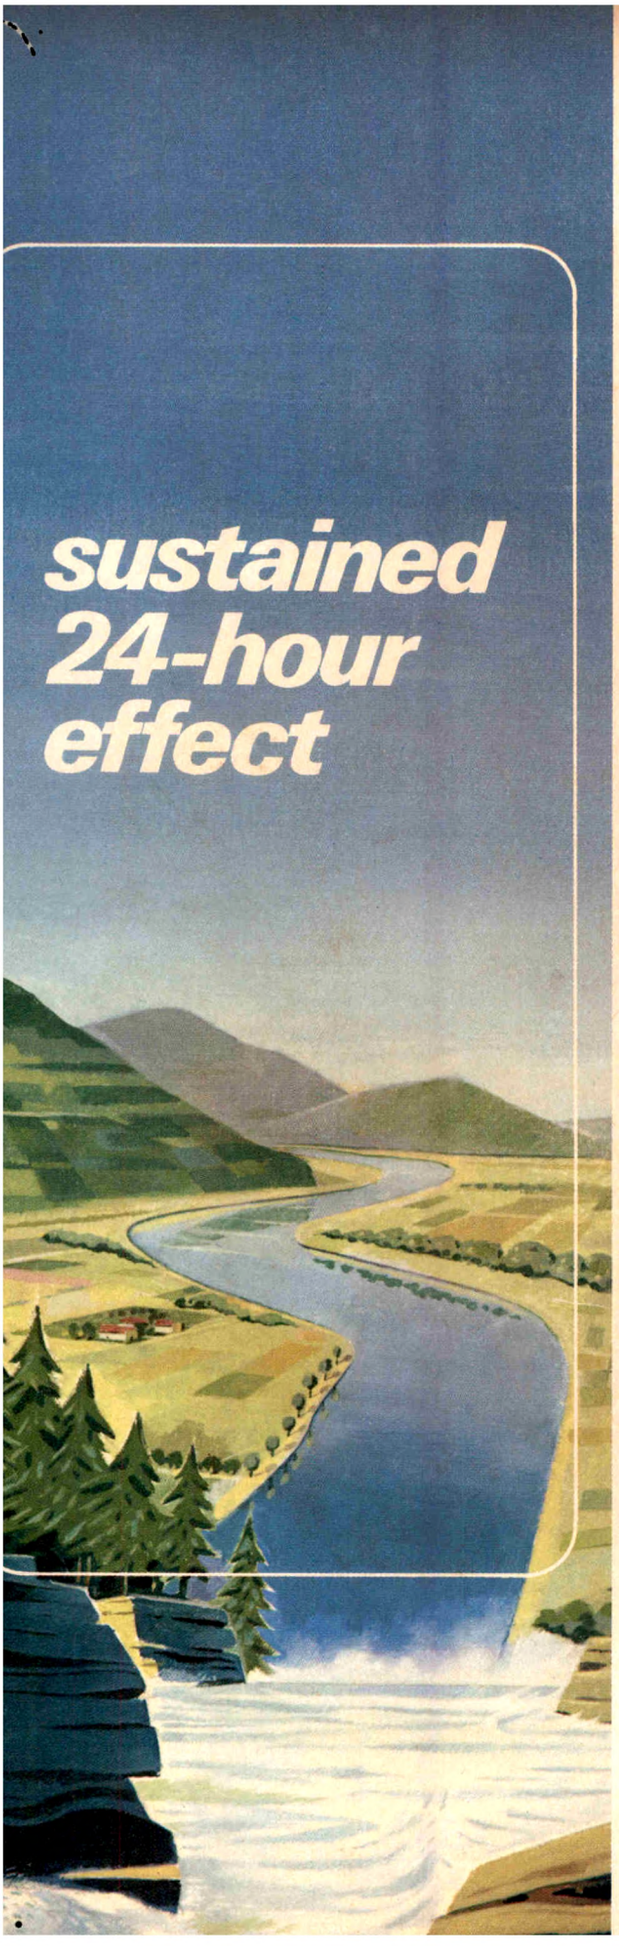
In mild to moderate edema of CHF.
DIULO™ 10 MG
(METOLAZONE)
rapid, moderately
potent diuresis



Diulo (metolazone) 10mg Indicated for use in chronic CHF

In acute pulmonary edema, dramatic volume depletion is desirable. That's why agents capable of producing profound diuresis within a few hours are indicated. But where smooth, prolonged effect is desirable – as in patients with chronic CHF, whether they be bedridden and elderly, ambulatory, or have low GFRs – a single, oral, therapeutic dose of Diulo produces effective natriuresis for up to 24 hours.

With Diulo 10 mg, your patient with chronic CHF benefits from effective diuretic action. But unlike those receiving more potent diuretics, patients receiving Diulo are not "wrung out" in two or three hours.

Although the conditions of some patients can be adequately controlled with a 5-mg dose of Diulo, one 10-mg tablet daily can provide effective diuresis around the clock in your patients with CHF, including those with paroxysmal nocturnal dyspnea.

DIULO™ (metolazone) 2½-mg., 5-mg. and 10-mg. tablets *Before prescribing, see complete prescribing information. The following is a brief summary:* ***Indications:*** *Diulo (metolazone) is an antihypertensive diuretic indicated for the management of mild to moderate essential hypertension as sole therapeutic agent and in the more severe forms of hypertension in conjunction with other antihypertensive agents. Also, edema associated with heart failure and renal disease.* ***Contraindications:*** *Anuria, hepatic coma or precoma; allergy or sensitivity to metolazone.* ***Warnings:*** *In theory, cross-allergy may occur in patients allergic to sulfonamide-derived drugs, thiazides or quinethazone. Hypokalemia may occur, and is a particular hazard in digitalized patients; dangerous or fatal arrhythmias may occur. Azotemia and hyperuricemia may be noted or precipitated. Considerable potentiation may occur when given concurrently with furosemide. When added to other antihypertensives, the dosage of the other agents should be reduced. Use with potassium-sparing diuretics may cause potassium retention and hyperkalemia. Administration to pregnant women or those of childbearing age requires that potential benefits be weighed against possible hazards to the fetus. Metolazone appears in the breast milk. Not recommended for pediatric use.* ***Precautions:*** *Perform periodic examination of serum electrolytes, BUN, uric acid, and glucose. Observe patients for signs of fluid or electrolyte imbalance, hyponatremia, hypochloremic alkalosis and hypokalemia. These determinations are particularly important when there is excessive vomiting or diarrhea, or when parenteral fluids are administered. Patients treated with diuretics or corticosteroids are susceptible to potassium depletion. Caution should be observed when administering to patients with gout or hyperuricemia or those with severely impaired renal function. Insulin requirements may be affected in diabetics, and hyperglycemia and glycosuria may occur in latent diabetes. Chloride deficit and hypochloremic alkalosis may occur. Orthostatic hypotension may occur. Dilutional hyponatremia may occur.* ***Adverse Reactions:*** *Constipation, nausea, vomiting, anorexia, diarrhea, bloating, epigastric distress, intrahepatic cholestatic jaundice, hepatitis, syncope, dizziness, drowsiness, vertigo, headache, orthostatic hypotension, excessive volume depletion, hemoconcentration, venous thrombosis, palpitation, chest pain, leukopenia, urticaria, other skin rashes, dryness of mouth, hypokalemia, hyponatremia, hypochloremia, hypochloremic alkalosis, hyperuricemia, hyperglycemia, glycosuria, raised BUN or creatinine, fatigue, muscle cramps or spasm, weakness, restlessness, chills, and acute gouty attacks.* ***Usual Initial Once-Daily Dosages:*** *Mild to moderate essential hypertension – 2½ to 5 mg.; edema of cardiac failure – 5 to 10 mg.; edema of renal disease – 5 to 20 mg. Dosage adjustment is usually necessary during the course of therapy.* ***How Supplied:*** *Tablets, 2½, 5 and 10 mg.; in bottles of 100 and 500, and cartons of 100 unit-dose individually blister-sealed tablets.*

EW
LOTRIX®
)TASSIUM CHLORIDE)
)W-RELEASE TABLETS 10 mEq •

CRIPTION KLOTRIX is a film-coated (not enteric-coated) tablet containing 750 mg potassium ide (equivalent to 10 mEq) in a wax matrix. This formulation is intended to provide a olled release of potassium from the matrix to minimize the likelihood of producing high ized concentrations of potassium within the gastrointestinal tract.

CATIONS— BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND EDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS ULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE ID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in alis intoxication and in patients with hypokalemic familial periodic paralysis.
r prevention of potassium depletion when the dietary intake of potassium is inadequate in the wing conditions: Patients receiving digitalis and diuretics for congestive heart failure; tic cirrhosis with ascites; states of aldosterone excess with normal renal function; sium-losing nephropathy, and certain diarrheal states.
e use of potassium salts in patients receiving diuretics for uncomplicated essential hyper- on is often unnecessary when such patients have a normal dietary pattern. Serum potassium ld be checked periodically, however, and, if hypokalemia occurs, dietary supplementation potassium-containing foods may be adequate to control milder cases. In more severe cases lementation with potassium salts may be indicated.

TRAINDICATIONS In patients with hyperkalemia, since a further increase in serum potassium entration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of llowing conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the adminis- on of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
matrix potassium chloride preparations have produced esophageal ulceration in certain ac patients with esophageal compression due to enlarged left atrium.
olid dosage forms of potassium supplements are contraindicated in any patient in whom there use for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium lementation should be with a liquid preparation.

NINGS Hyperkalemia: In patients with impaired mechanisms for excreting potassium, nistration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most nonly in patients given potassium intravenously but may also occur when given orally. Poten- fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in nts with chronic renal disease, or any other condition which impairs potassium excretion res particularly careful monitoring of the serum potassium concentration and appropriate ge adjustment.
raction with potassium-sparing diuretics: Hypokalemia should not be treated by the omitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolac- or triamterene), since the simultaneous administration of these agents can produce re hyperkalemia.
rointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative ins of the small bowel and deaths. These lesions are caused by a high localized concentration tassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and by produces obstruction, hemorrhage, or perforation. KLOTRIX is a wax-matrix tablet formu- to provide a controlled rate of release of potassium chloride and thus to minimize the possi- of a high local concentration of potassium ion near the bowel wall. While the reported small-bowel lesions is much less with wax-matrix tablets (less than one per 0 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 nt-years) cases associated with wax-matrix tablets have been reported both in foreign coun- and in the United States. In addition, perhaps because the wax-matrix preparations are not ric-coated and release potassium in the stomach, there have been reports of upper gastroin- nal bleeding associated with these products. The total number of gastrointestinal lesions ins less than one per 100,000 patient-years. KLOTRIX should be discontinued immediately the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal , distention, or gastrointestinal bleeding occurs.
abolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an izing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

CAUTIONS Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a nt with a clinical history suggesting some cause for potassium depletion. In interpreting the m potassium level, the physician should bear in mind that acute alkalosis *per se* can produce kalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can ease the serum potassium concentration into the normal range even in the presence of a total body potassium. Treatment of potassium depletion particularly in presence of cardiac ase, renal disease, or acidosis, requires careful attention to acid-base balance and appropri- monitoring of serum electrolytes, electrocardiogram and clinical status of patient.

ERSE REACTIONS Most common to oral potassium salts: nausea, vomiting, abdominal omfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are managed by diluting the preparation further, taking the dose with meals, or reducing the dose. of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). e also have been reports of upper and lower gastrointestinal conditions including obstruction, ding, ulceration and perforation (see Contraindications and Warnings); other factors known to ssociated with such conditions were present in many of these patients. Skin rash has been rted rarely.

AGE Usual dietary intake potassium by the average adult is 40 to 80 mEq per day. Potassium etion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium the total body store.
ge must be adjusted to the individual needs of each patient but is typically in the range of nEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of ssium depletion.
e: KLOTRIX slow-release tablets must be swallowed whole and never crushed or chewed.
V SUPPLIED Bottles of 100.

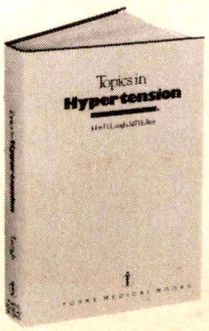
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by
John H. Laragh, MD
Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

Minneapolis, Minnesota

Observations made in detecting left ventricular thrombus with two dimensional echocardiography in 25 patients are reviewed. In 20 patients thrombus was documented on angiography, surgery, postmortem examination or serial two dimensional echocardiographic findings; in the remaining five patients two dimensional echocardiographic findings of thrombus were unequivocal. In all 25 patients wall motion abnormalities ranging from hypokinesia to frank dyskinesia were present at the site of the thrombus. Twenty-three patients had an apical thrombus; two had thrombus adjacent to the inferior wall. Clear delineation of the endocardium and thrombus margin was considered essential to the correct diagnosis of thrombus. Both intracavitary motion of the thrombus margin and a layering effect were noted infrequently although they were of benefit in identifying an intracardiac mass as thrombus. In addition, serial evaluations were helpful in establishing the correct diagnosis.

False positive diagnoses can be minimized if one understands certain technical limitations of this method and correctly identifies apical structures that are not thrombi. Axial and lateral resolution problems inherent with this technique can produce intracavitary echoes that may simulate thrombi. In addition, normal or pathologic structures at the apex may also simulate thrombi. These structures include the papillary muscles, muscular trabeculae, chordal structures and tangential information from normal myocardium. Varying the sector orientation or acoustic window, or both, will aid in correctly identifying these structures and distinguishing them from left ventricular thrombi.

Left ventricular thrombus is a common postmortem finding in the settings of acute myocardial infarction,[1–3] congestive cardiomyopathy[3] and left ventricular aneurysm.[1,3,4] However, before the availability of two dimensional echocardiography, the presence of thrombus became clinically apparent only if an embolic event occurred or if detection was made by contrast ventriculography. Embolic events that occur in these clinical conditions can cause significant morbidity and occasional death. Randomized trials of anticoagulation in acute myocardial infarction have not shown a significant decrease in mortality in the groups receiving therapy,[5–7] but a significant reduction in the incidence of systemic embolism has been noted.[6,7] The presumed mechanism for embolic events during acute myocardial infarction is mural thrombus followed by peripheral embolization. Two dimensional echocardiography is a method that can potentially detect left ventricular thrombus before embolization. Thus, this technique may make it possible to institute appropriate therapy in patients after infarction and prevent or decrease the incidence of embolization.

When two dimensional echocardiography is applied to the evaluation of patients at risk for left ventricular thrombus, it is important to establish prospectively guidelines for the accurate diagnosis of such

ırombus. From angiographic, surgical and post-ıortem correlative observations, we have found that vo dimensional echocardiography is a sensitive :chnique for detecting such thrombus. An appre-ation of the inherent limitations of two dimensional :hocardiography and knowledge of left ventricular ıatomy are necessary to avoid the misdiagnosis of ırombus. In this review we note our observations in ətecting and characterizing left ventricular ırombus using two dimensional echocardiography 25 patients with particular emphasis on avoidance ' false positive interpretations.

Methods

Study patients: These observations were made from a se-ɛs of 2,657 consecutive two dimensional echocardiographic udies performed at this institution over a 27 month period. ɔrty-one patients with echocardiographic findings consid-ed highly suggestive (n = 25) or characteristic (n = 16) of left ıntricular thrombus were identified by two experienced hocardiographers.

Imaging technique: Patients were studied with either a ırian V-3000 electronic phased array ultrasonoscope or a ɔrtable Advanced Technology Laboratory (ATL) Mark III echanical ultrasonoscope. A 2.5 megahertz transducer was utinely used with the Varian V 3000 and a 3 megahertz ınsducer with the ATL Mark III. A systematic examination ıs performed utilizing parasternal, apical and subcostal oustic windows with varying sector orientations.[8] The apical ecordial window was most useful in detecting left ventricular rombus because most such thrombi occurred at the apex. ɔr the apical views patients were examined with the head ghtly elevated and in the left lateral decubitus position with e transducer placed at the point of maximal impulse. With the echocardiographic beam directed toward the left atrium, routine two and four chambered views were obtained.[9] To provide a thorough examination of the apex, positions intermediate between these two standard sector orientations as well as an apical short axis view (Fig. 1) were also obtained. Shallow depth of field settings of 7 and 9 cm for the apical views with the mechanical sector scanner were particularly helpful in defining apical anatomy. We found the mechanical scanner superior to the phased array ultrasonoscope for defining apical anatomy because near field artifact was minimal and adequate resolution maintained. Multiple gain and reject settings were also utilized to ensure definition of the pericardium, epicardium, endocardium, and thrombus margin.

Diagnostic classification of left ventricular thrombus (Table I): Detection of left ventricular thrombus with two dimensional echocardiography depends upon the quality of the examination. We developed a grading scale that incorporates the quality of the examination in classifying the index of suspicion for left ventricular thrombus (Table I). The scale ranges from 0 to 4. *Grade 0* indicates a good quality examination of the left ventricle with no evidence for thrombus. Left ventricular echo densities may be present, but must have characteristics of ventricular structures other than thrombus. Such structures include the papillary muscles, muscle trabeculae and chordal structures. *Grade I* indicates an examination with an echo density in the left ventricle that is believed to be papillary muscle, muscle trabeculae or chordal structures rather than thrombus. However, the technical quality of the examination is not ideal, and does not permit a 0 grade. *Grade II* represents an examination with a definite echo density with nonspecific features present in the left ventricle. The quality of the examination or the nonspecific character of the echo mass prohibits further categorization. *Grade III* represents an examination demonstrating an echo density in the left ventricle highly suspicious of thrombus, but the quality of the

A small pericardial effusion (PE) is also present. LV = left ventricular cavity; RV = right ventricular cavity.

TABLE I

Two Dimensional Echocardiographic Classification for Suspicion of Left Ventricular Thrombus

Class	Criteria
0	Thrombus definitely not present; technically good examination.
I	Definite left ventricular echo mass but probably not thrombus; examination technically not good enough to classify as 0 (probably represents cardiac structure other than thrombus).
II	Definite abnormality, but of uncertain nature.
III	Findings highly suspicious for thrombus; examination technically not adequate to classify as diagnostic.
IV	Findings characteristic of thrombus; technically good or adequate examination.

examination does not allow definitive characterization. *Grade IV* indicates an examination characteristic for left ventricular thrombus. An echo-dense left ventricular mass is present that is discrete from the endocardial surface and has other characteristics of thrombus (Table II).

Results

Of the 41 patients identified as having left ventricular thrombus on two dimensional echocardiography, 16 had a grade IV examination. In 11 of these 16 patients thrombus was confirmed with angiography, surgery, postmortem examination or serial two dimensional echocardiographic studies (Table III). In addition, in 9 of the 25 patients whose examinations were judged highly suggestive of thrombus (grade III), thrombus was also confirmed (Table III). Although none of the remaining 16 patients with highly suggestive examinations were shown to have a false positive study, they are not discussed further because positive confirmation was not obtained.

The observations presented in this report are thus based on the echocardiographic findings of 25 patients—16 with characteristic two dimensional echocardiographic examinations for thrombus and 9 patients with highly suggestive examinations whose diagnosis of thrombus was confirmed either by independent means or by serial two dimensional echocardiograms.

Documentation of Thrombus

Left ventricular angiography: In seven patients left ventriculography demonstrated apical filling defects consistent with thrombus[10] within 1 week of the two dimensional echocardiogram (Table III). In another three patients with a large left ventricular aneurysm ventriculograms were interpreted as negative for thrombus although the two dimensional echocardiogram indicated thrombus (grade III in one and grade IV in two). All three patients underwent aneurysmectomy within 48 hours of the positive echocardiographic study and thrombus was confirmed in each.

Surgery: Six patients had a surgical procedure that confirmed or supported the echocardiographic diagnosis of left ventricular thrombus (Table III). Three had left ventricular aneurysmectomy, and thrombus was confirmed in the aneurysmal segment in each. The remaining three patients had operative findings that supported the clinical and echocardiographic diagnoses of left ventricular thrombus. One had a left femoral arterial embolectomy 4 days after acute anterior myocardial infarction, and left ventriculography confirmed the presence of thrombus. After embolectomy this patient was placed on anticoagulant therapy and serial two dimensional echocardiographic studies demonstrated resolution of the thrombus. Another patient with recent transmural inferior myocardial infarction presented with evidence of acute occlusion of the right femoral artery. After embolectomy, anticoagulant therapy was not instituted and the patient returned several months later with multifocal transient cerebral ischemic attacks followed by a right-sided cerebrovascular accident. Further two dimensional echocardiography demonstrated a persistent left ventricular mass highly suggestive of thrombus. Another patient with long-standing congestive cardiomyopathy experienced severe abdominal pain while hospitalized for congestive heart failure. Exploratory laparotomy demonstrated a discrete segment of infarcted small bowel, and an embolus was removed from the superior mesenteric artery.

TABLE II

Two Dimensional Echocardiographic Features of Left Ventricular Thrombus

1. Associated wall motion abnormality.
2. Apical location frequent but not exclusive.
3. Distinct thrombus margin.
4. Acoustically distinct from underlying myocardium.
5. Free motion of an intracavitary thrombus margin.
6. Variation noted on serial examination.

Postmortem examination: Postmortem examination confirmed left ventricular thrombus in four patients with a positive echocardiographic examination (grade III in one and grade IV in three, Table III). Two patients had a recent anterior myocardial infarction and the other two had congestive cardiomyopathy.

Serial two dimensional echocardiographic studies: Serial echocardiographic evaluation was helpful in diagnosing a left ventricular mass as thrombus in seven patients. In four of these patients, the left ventricular mass thought to represent thrombus disappeared during follow-up studies while they were receiving anticoagulant therapy (Table III). In two of these four left ventriculography at the time of the initial positive echocardiographic study also confirmed thrombus. In another three patients, left ventricular thrombus developed during serial evaluation during the course of an acute anterior myocardial infarction.

Thrombi without independent confirmation: Of the 16 patients whose two dimensional echocardiograms were characteristic of thrombus (grade IV), 11 had thrombi that were documented by an independent technique or serial echocardiography. The five patients without further documentation of thrombus were also included in these observations because of unequivocal

hocardiographic features of left ventricular thrombus Table III, Fig. 1 to 5). Three were imaged during the urse of acute anterior myocardial infarction while the maining two had congestive cardiomyopathy.

chocardiographic Characteristics and Associated ndings of Left Ventricular Thrombus

Wall motion abnormalities: All patients had wall otion abnormalities adjacent to their thrombus. Wall otion was hypokinetic in two patients with congestive rdiomyopathy. Akinesia was noted in the remaining ree patients with congestive cardiomyopathy as well in several patients with ischemic heart disease. yskinesia (systolic expansion) of a segment of the ntricular wall adjacent to the thrombus was common. most patients with dyskinesia, the diastolic contour the ventricle was normal; in six patients the diastolic contour was clearly abnormal because of an expanded wall segment, and all six had a left ventricular aneurysm. Three of the six underwent successful left ventricular aneurysmectomy; two others died and both had an aneurysm containing thrombus confirmed at postmortem examination. In the remaining patient congestive cardiomyopathy developed with a persistent but markedly smaller mural thrombus at the 1 year follow-up study.

Location of thrombus: Twenty-three patients had thrombus located at the apex and all thrombi were imaged by the apical acoustic window. Two patients had thrombus located along the inferior wall; one in an area of akinesia and the other in a pseudoaneurysm.

Relation to left ventricular wall: The relation of thrombus to the endocardial surface and left ventricular cavity was also analyzed (Table III). Thrombi could be

classified as mural (Fig. 6) or protruding (Fig. 1 and 2). Flat thrombi parallel to the endocardial surface were classified as mural, and thrombi that projected into the left ventricular cavity as protruding. These classifications were not mutually exclusive; three patients had evidence of both patterns. Of the remaining 22 thrombi, 13 were mural and 9 protruding.

The echocardiographic dimensions of the protruding thrombi varied, with the smallest detected thrombus measuring 1.5 by 1.5 by 2.5 cm (Table III, Patient 17). The dimensions of mural thrombi were more difficult to quantitate because of their wide area of contact with the endocardial surface. The smallest thickness of an identified mural thrombus was approximately 1 cm (Table III, Patient 6).

Motion of the intracavitary thrombus margin: Only four patients had evidence for free intracavitary motion of a thrombus margin. Two of these four patients had a thrombus with ragged margins that moved in a limited fashion in the left ventricular cavity during the cardiac cycle (Fig. 4). The portions with free motion were of the same echo density as the remainder of the

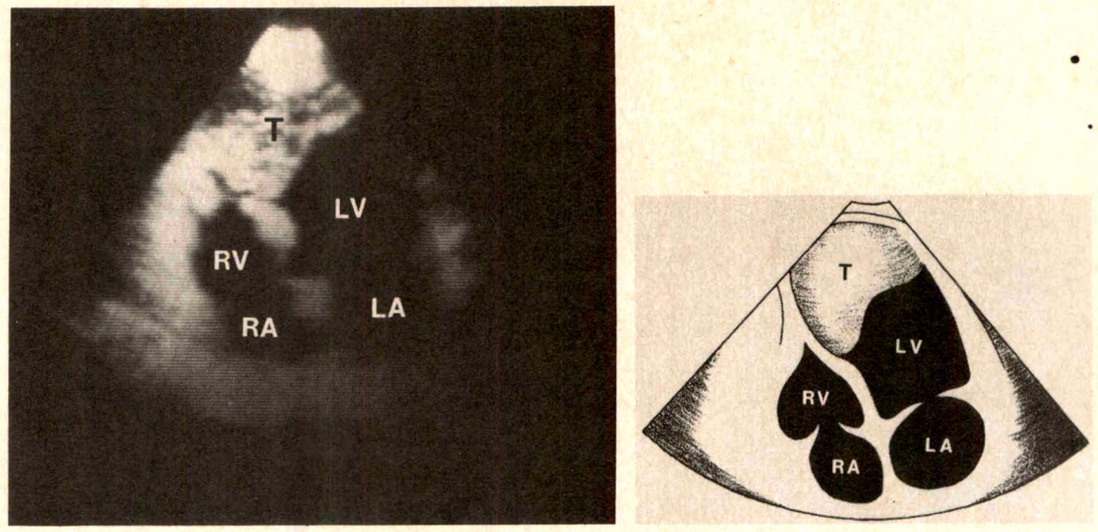

FIGURE 3. Patient 21. Apical four chambered view of echocardiogram demonstrating a large mural thrombus (T) 10 days after acute anterior infarction. Note the distortion of the apical contour indicating aneurysm formation. LA = left atrium; RA = right atrium; other abbreviations as in Figure 1.

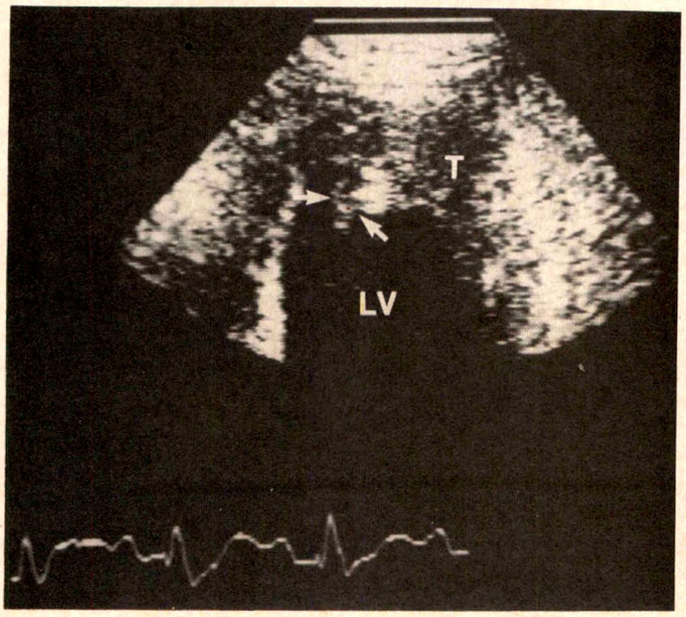

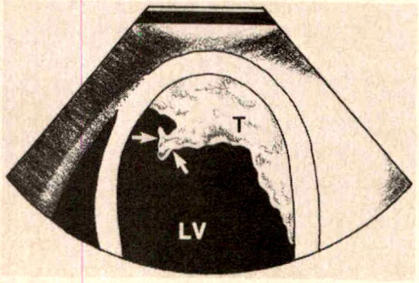

FIGURE 4. Patient 23. Apical two chambered view at shallow range setting. A left ventricular thrombus (T) with evidence of free motion of an intracavitary margin is present. The portion of the thrombus indicated by the **arrows** demonstrated a limited degree of motion in the left ventricular cavity (LV). This portion of the thrombus is of the same echo density as the remainder of the thrombus.

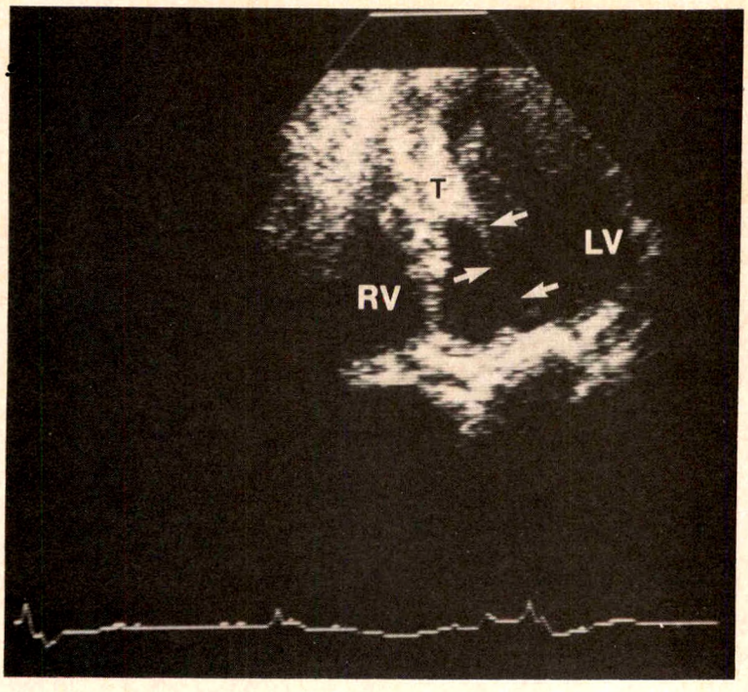
hrombus. Two other patients had a thrombus that demonstrated a different type of free intracavitary motion. In these two, large dynamic masses of low amplitude echoes were present in the left ventricular cavity and appeared associated with a discrete thrombus (Fig. 5). These masses had a veil-like appearance and swirled in the left ventricular cavity.

Echo density of intracavitary thrombus margin: Several patients demonstrated evidence of a layered thrombus with variations in echo density. In these patients the most echo-dense layer of thrombus was adjacent to the left ventricular cavity (Fig. 6) and ranged from 2 to 5 mm in thickness. Each of these patients had a mural pattern.

Comment

An increasing amount of evidence[11–17] indicates that two dimensional echocardiography is a useful and perhaps the preferred method of detecting left ventricular thrombus. These data and our present results indicate that two dimensional echocardiography allows detection of left ventricular thrombi that might not be clinically manifest or detected by other available methods. It is apparent that two dimensional echocardiography has



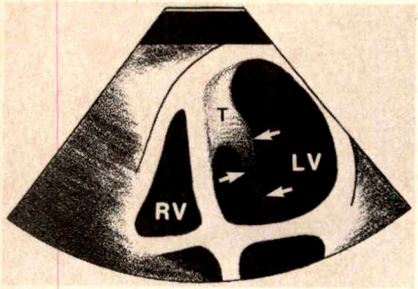


FIGURE 5. Patient 25. Apical two chambered view. A protruding thrombus (T) is present at the apical-septal junction. A large swirling mass of low density echoes (**arrows**) that moved freely in the left ventricle is also present. Abbreviations as in Figure 1.

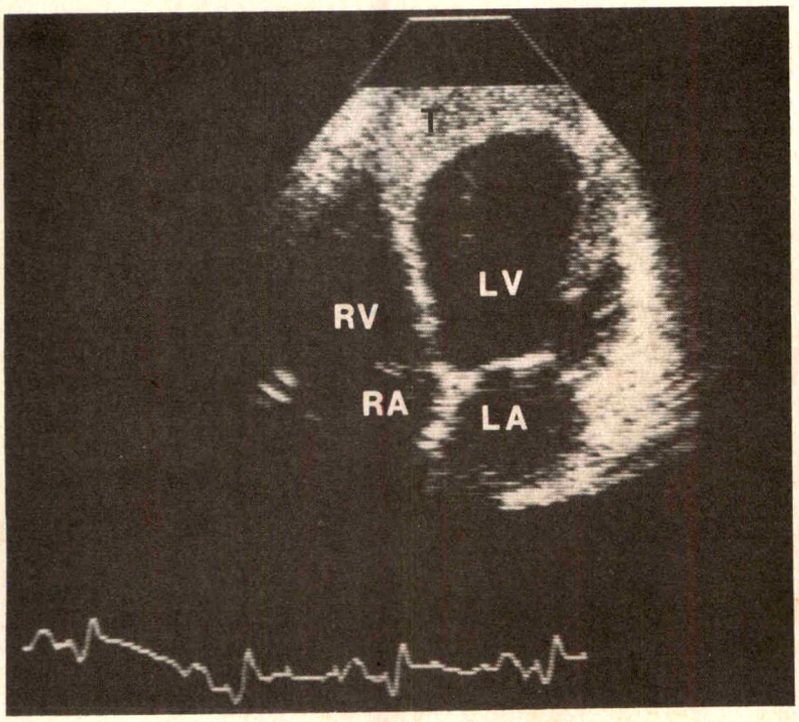

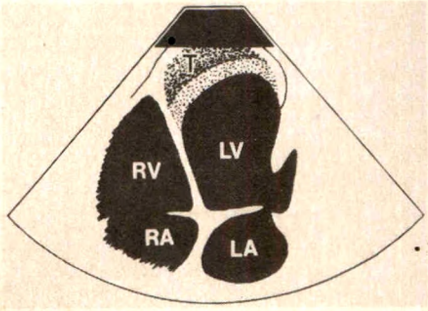

FIGURE 6. Patient 11. Apical four chambered view demonstrating a mural thrombus (T) with layering. the potential to provide previously unavailable information regarding the natural history and response to therapy of left ventricular thrombi. Such information will ultimately enhance our understanding of left ventricular thrombi; however, this ability to identify thrombi raises important questions regarding patient management and therapy. Hence, every precaution should be taken to ensure the accuracy of the diagnosis of thrombus by this technique.

Although the reliability of two dimensional echocardiography has been established, guidelines for accurate diagnosis and steps to avoid a false-positive diagnosis have not been stressed. In this report we summarize various two dimensional echocardiographic characteristics and associated features of left ventricular thrombus in 25 patients. In addition, we discuss potential causes of a false positive diagnosis and ways of avoiding these errors.

Two Dimensional Echocardiographic Features of Left Ventricular Thrombus (Table II)

Associated wall motion abnormality: Relative stasis of blood in areas of abnormal wall motion and endocardial injury have been implicated in the genesis of left ventricular thrombus.[1] Pathologic evidence of left ventricular wall abnormalities adjacent to thrombus has been noted,[1] and wall motion abnormalities have been observed angiographically in patients with left ventricular thrombus.[10] In our experience thrombus in the left ventricle is *always* associated with wall motion abnormalities. However, wall motion abnormalities associated with thrombus varied from generalized hypokinesia in patients with congestive cardiomyopathy to frank dyskinesia in patients with left ventricular aneurysm. We are reluctant to consider the diagnosis of left ventricular thrombus in the absence of some wall motion abnormality.

Twenty-one of our patients had ischemic heart disease, with prior myocardial infarction and wall motion abnormalities. Sixteen had anterior and five had inferior infarction. This association of anterior infarction and thrombus is consistent with previous pathologic,[1] angiographic[10] and echocardiographic[12–14] reports. Three of the five patients with inferior infarction had a thrombus at the apex, and each of these three had apical wall motion abnormalities. The other two patients had definite inferior wall abnormalities where the thrombus was located.

Thrombus location: Previous autopsy studies[1–3] have indicated that left ventricular thrombus is most frequently located at the apex. In 23 of our 25 patients left ventricular thrombus was at the apex; in the remaining 2 it was located along the inferior wall. The predilection for thrombus formation at the apex suggests that abnormal wall motion in this area results in a greater focal stasis of intracavitary blood than does comparable wall motion abnormality in other areas of the ventricle. Of importance from a technical aspect was the fact that all thrombi were imaged from the apical acoustic window. In contrast to observations made by Meltzer et al.,[13] we have found that the left ventricular apex cannot routinely be adequately examined by the subcostal window, although this approach may support or confirm findings noted on apical views.

Distinct thrombus margin: The identification of thrombus and its relation to the endocardial surface is obvious in some cases (Fig. 1), but in many cases the distinction is more difficult, particularly when a mass

ıat is not obviously thrombus is imaged at the left entricular apex. In these cases an attempt should be ıade to identify pericardium, epicardium, endocardium ıd thrombus margins. An accurate assessment of these ;ructures at the left ventricular apex can be challeng-ıg, particularly in the setting of a segmental wall ab-ormality. Multiple gain and reject settings will aid in lentifying apical anatomy, but in our experience the ıost useful technique employs shallow depth settings rovided that near field artifact is minimal and ade-ıate resolution maintained. We have found the me-ıanical scanner superior to the phased array ultraso-ɔscope in obtaining high resolution imaging of the ɔex. Proper identification of the pericardium is helpful nce it establishes a landmark. The pericardium is latively stationary at the apex and may be separated om the epicardium by an echo-free space when peri-ırdial fluid or thickening is present (Fig. 1). Apical wall ɔicardial and endocardial surfaces move in a parallel shion during the cardiac cycle when imaged from the ɔical window, although varying degrees of systolic ıickening or thinning be noted.

Wall thickness should be assessed particularly in the tting of left ventricular aneurysm. Usually the walls a discrete aneurysm are thin; hence, the finding of ɔrmal wall thickness in an aneurysmal segment should ise the suspicion of mural thrombus.[12] Careful ex-nination of the apex with shallow depth settings may ıen allow accurate distinction of thrombus from en-ɔcardium. Another difficulty in identifying thrombus argins related to width of the ultrasonic beam. Be-use the beam has a certain width, it is possible to ob-in images of adjacent myocardium within the left ntricular cavity.[18] In our experience, these spurious hoes are common with wall motion abnormalities, rticularly when echo-dense myocardial scar is sent. Such spurious echoes can simulate the margins a thrombus. Correct identification of these echoes as tifact can be made by obtaining multiple views to nfirm apical contour and anatomy.

Acoustic characterization of thrombus: Although e acoustic characteristics of thrombi may differ, the ho density of thrombi is usually greater than that of ljacent myocardium.[14] We observed that protruding rombi tend to be relatively echo-dense (Fig. 1 and 2) ıile mural thrombi in general tend to be less echo-ense (Fig. 6) and hence cause more difficulty in dis-nguishing thrombus from myocardium. Individual rombi may have heterogenous areas of echo density at occasionally give the appearance of a layered pat-rn. When a layered pattern is observed, the most ho-dense portion of the left ventricular thrombus is ually along the intracavitary margin (Fig. 6). This area esumably represents the most recently formed por-ɔn of the thrombus. Perhaps the composition or ar-itecture of recently formed thrombus results in a eater echo density than that of older thrombus. In pport of this concept is the imaging of highly echo-nse thrombi within 10 days of acute transmural in-rction in 10 of our 25 patients. The portion of the rombus between the intracavitary border and endo-rdium should be echo-dense in comparison with in-tracavitary blood unless a portion of the thrombus has liquified. If liquification of a portion of the thrombus has occurred, then an echo-free space may be present within the substance of the thrombus.

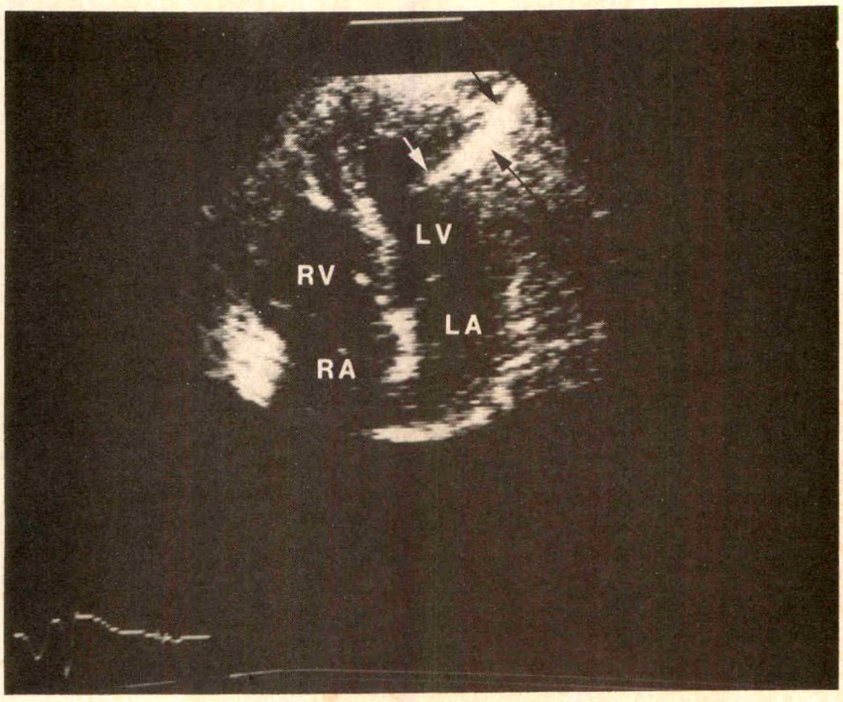
Intracavitary motion of thrombus margin: Unrestricted motion of an intracavitary thrombus margin[13,14] has not been common in our experience and occurred in only 4 of our 25 patients. In two of the four, a small ragged portion of the thrombus along the intracavitary border showed limited motion within the left ventricular cavity (Fig. 4). Because this pattern of motion has not been observed in any other circumstance, it may aid in correctly identifying an echo mass as thrombus. The other two patients demonstrated a large, low density swirling mass of intracavitary echoes in addition to a discrete thrombus (Fig. 5). The origin of these swirling echoes is not clear. We have noted similar echoes in cases where no discrete thrombus was identified; hence they may represent a phenomenon related to early thrombus formation or even low flow. In any event their presence should prompt a thorough search for discrete thrombus. Both patterns of intracavitary motion associated with these thrombi were easily distinguished from chordal structures, papillary muscles and vegetative lesions.

Variation noted on serial studies: Observations made during serial two dimensional echocardiographic studies of patients with a left ventricular mass have been helpful in identifying the mass as thrombus. The complete disappearance of a mass on serial examinations, as noted in four patients on chronic anticoagulant therapy, or the development of an echo-dense mass with characteristics of thrombus during acute myocardial infarction, as noted in three patients, provides support for the diagnosis of left ventricular thrombus.

Although the echocardiographic features of a left ventricular mass may be obviously characteristic of thrombus, there are instances where these features are not specific or the quality of the images is suboptimal and hence the examination cannot be considered characteristic for thrombus. We have used a grading scale to indicate our index of suspicion for left ventricular thrombus. This grading scale (Table I) incorporates the echocardiographic features of or associated with left ventricular thrombus (Table II) as well as a subjective evaluation of the quality of images obtained. This classification system provides a practical method of conveying the index of suspicion for thrombus and a convenient method for prospectively examining diagnostic accuracy. We have been pleased with the diagnostic accuracy of examinations classified as highly suggestive or characteristic of left ventricular thrombus and the lack of false positive interpretations to date. Although this particular approach may be unique for our laboratory, we believe it is most important for laboratories to evaluate on an ongoing basis their accuracy in this difficult area of two dimensional echocardiographic interpretation.

Avoidance of False Positive Studies

False positive examinations may be the result of either problems inherent in the ultrasonic technique itself



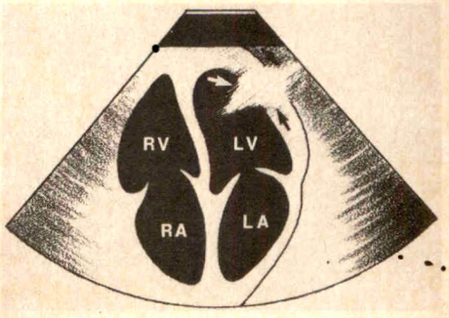


FIGURE 7. Apical two chambered view demonstrating a strong echo reflector along the distal lateral wall (**arrows**) which causes a spurious intracavitary echo simulating a thrombus margin. Abbreviations as in Figures 1 and 3.

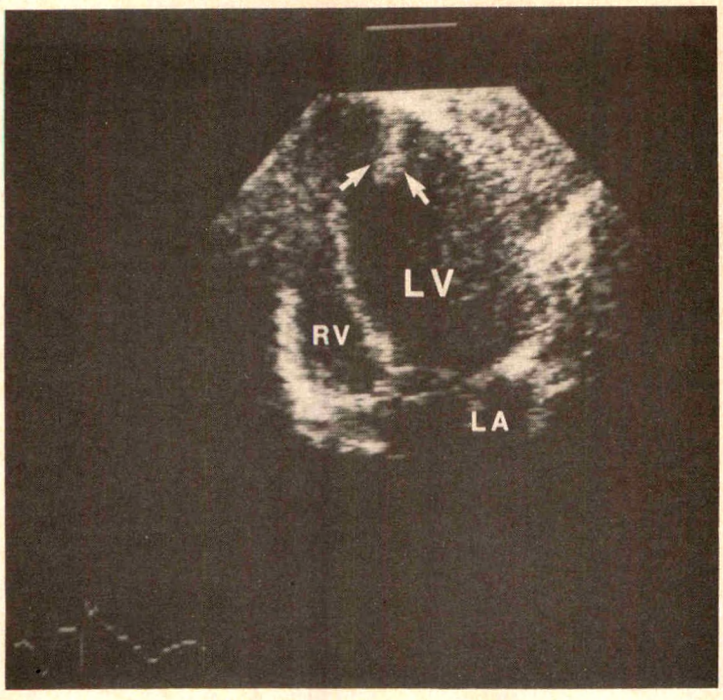
or errors in correctly identifying normal or pathologic structures at the left ventricular apex.

Ultrasonic technique and current instrumentation: Apical views are most useful in diagnosing left ventricular thrombi. The apex is only a few centimeters from the source of ultrasound in these views; hence, axial and lateral resolution in the near field are most important. Near field artifact, frequently a problem with phased array systems, must be minimized; otherwise, low gain settings are necessary and may not permit recognition of low reflective structures such as the endocardial surface or thrombus margin. In addition, spurious intracavitary echoes caused by structures outside the main axis of the ultrasonic beam can also cause considerable interpretative difficulty (Fig. 7).[18] This problem can frequently be solved by obtaining multiple sector orientations of the area in question. A true intracavitary echographic target such as a throm-



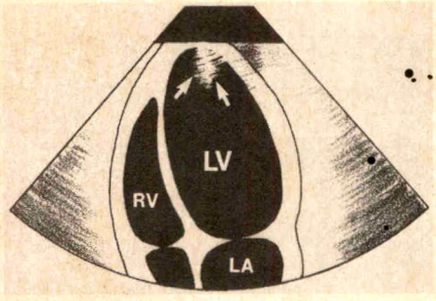


FIGURE 8. Apical four chambered view of a patient with previous infarction. Reverberation artifact from the apex is present (**arrows**) which simulates a protruding intracavitary thrombus. Arrows indicate this reverberation artifact. Abbreviations as in Figures 1 and 3.

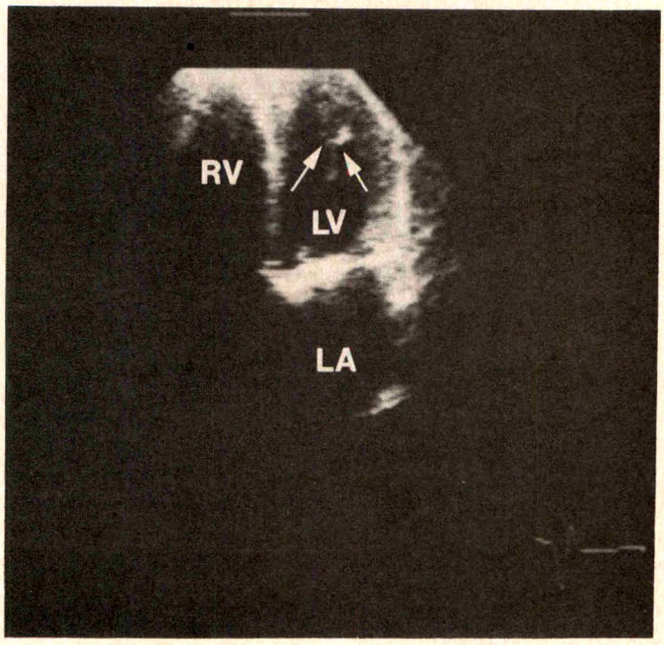

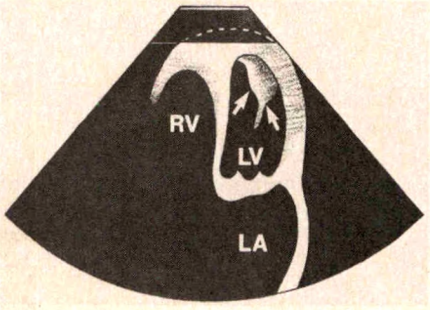

FIGURE 9. Apical two chambered view of a patient after mitral valve replacement. A partially amputated papillary muscle with chordal remnants is present (**arrows**) and simulates a thrombus. However, it is in the position of the papillary muscle, and no wall motion abnormality was present. Abbreviations as in Figures 1 and 3.

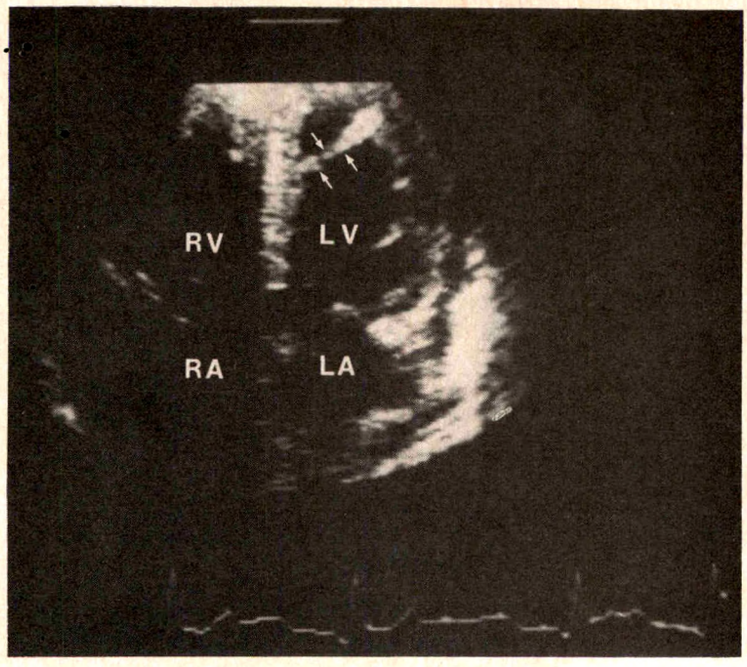
ıs or thrombus margin should have a constant and producible position in the left ventricular cavity, ıereas spurious echoes will show a change in position disappear when the sector orientation is altered. Very flective echographic targets such as an area of calcified yocardial scar can also be troublesome, not only be-use of lateral resolution difficulties caused by beam dth but also axial resolution problems secondary to verberation artifact (Fig. 8). These axial reverbera-ıns can usually be correctly identified since they ap-ar parallel to their source and exhibit parallel vertical tion. Again, changing acoustic window or sector or-ientation will be helpful in identifying these echoes as artifact.

Identification of normal or pathologic apical structures: Certain normal or pathologic structures, other than thrombus, may be located near the left ventricular apex and misconstrued as thrombus. Such structures include papillary muscles, muscle trabeculae, chordal structures and tangential left ventricular wall.

Papillary muscles: Papillary muscle identification usually causes little diagnostic dilemma. In the apical four chambered view, the posteromedial papillary



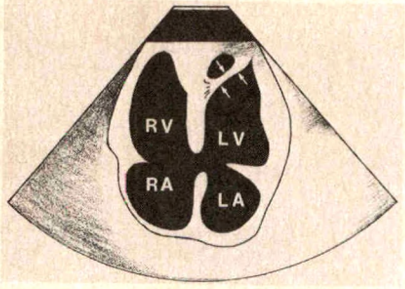


FIGURE 10. Apical four chambered view of a patient with left ventricular hypertrophy. A muscular bridge coursing from the lateral apical wall to the mid portion of the interventricular septum is noted (**arrows**). Note that an echo-free space is present on either side of this muscular bridge. Abbreviations as in Figures 1 and 3.

muscle appears along the septal aspect of the left ventricle near the junction of the middle and distal third of the interventricular septum. The anterolateral papillary muscle appears along the lateral left ventricular wall near the junction of the middle and distal third. When mitral valve replacement has been performed, a portion of the papillary muscles and their chordal structures may be partially amputated, and the remaining structures may be misinterpreted as thrombus (Fig. 9). A helpful finding in this situation is that the papillary muscles are located in their usual position and are not necessarily associated with left ventricular wall motion abnormality.

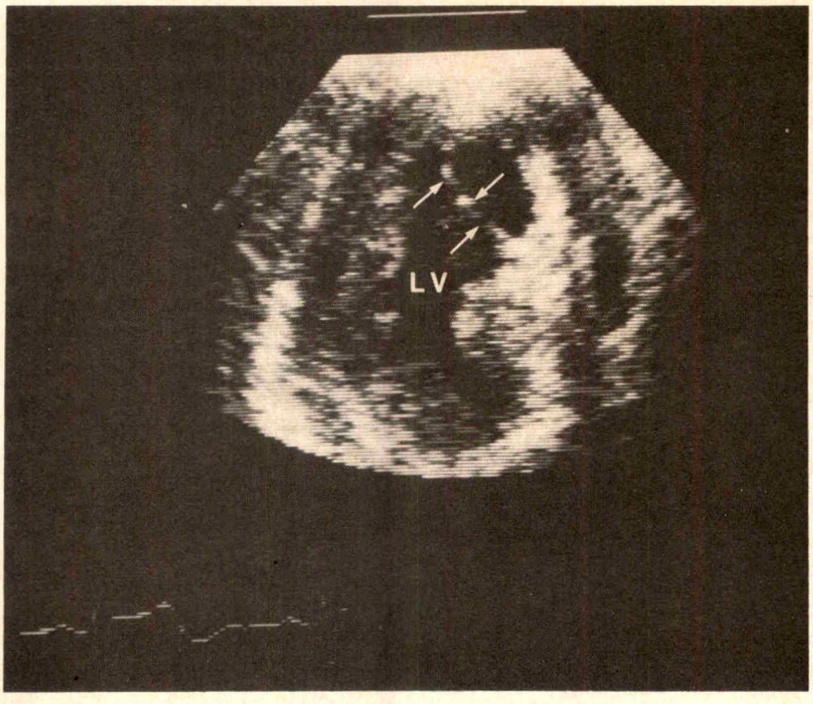
Muscle trabeculation: Heavy trabeculation at the apex frequently occurs with left ventricular hypertrophy and may present a confusing picture when attempting to examine the apex for possible thrombus. These trabeculations may appear as muscle bridges (Fig. 10) and can be present in any different arrangement in the left ventricle. Echo-free areas on each side on these bridges and lack of wall motion abnormality will aid in identifying these structures as trabeculation rather than thrombus.

Chordal structures: Chordal structures present in the left ventricle include true chordae tendineae and fine chord-like structures that interconnect muscle trabeculae. True chordae tendineae are imaged between the area of the papillary muscles and mitral valve leaflets and occasionally appear as bright fleeting echoes that dart into and out of the ultrasonic beam during the cardiac cycle. These echoes are discrete and may represent either diastolic buckling of individual chordae tendineae or echo planes perpendicular to different chordae during various portions of the cardiac cycle producing a fleeting echocardiographic pattern. The discrete nature of these echoes aids in their distinction from the low amplitude swirling masses of echoes occasionally associated with discrete left ventricular thrombus.

The chord-like structures connecting trabeculi can also be imaged in the left ventricle (Fig. 11). These have a fine string-like appearance with an echo-free area on each side. Both of these features aid in distinguishing these structures from thrombi. In addition, these chord-like structures are not necessarily associated with left ventricular wall motion abnormalities. However, they must be differentiated from the margin of a thrombus that has free intracavitary motion, and this distinction can be difficult. These chord-like structures are usually straightened during diastole but some buckling can occur with systole. In contrast, free margins of a thrombus assume varying positions during the cardiac cycle and demonstrate beat to beat variation in their motion (Fig. 5).

Tangential left ventricular wall: Occasionally tangential data will be obtained through normal ventricular muscle and simulate mural thrombus (Fig. 12). Complete examination with multiple sector orientations from the apical acoustic window will assist in correctly identifying these layered masses as tangential left ventricular wall rather than thrombus. This can also be a problem in sector planes parallel to the papillary muscle. Orientation of the echo plane parallel through a papillary muscle may simulate a mass protruding into the left ventricular cavity that can be confused with a protruding left ventricular thrombus.

In summary, left ventricular thrombi have certain characteristics in location, acoustic appearance and relation to underlying endocardium and myocardium that allow detection with two-dimensional echocardi-



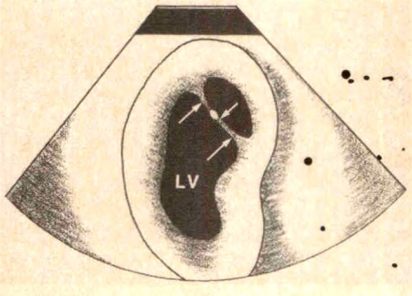


FIGURE 11. Apical cross-sectional view of a patient with left ventricular hypertrophy. A fine chordal structure is present (**arrows**) which courses across the apex. An echo-free space is present on either side of the string-like structure. LV = left ventricle.

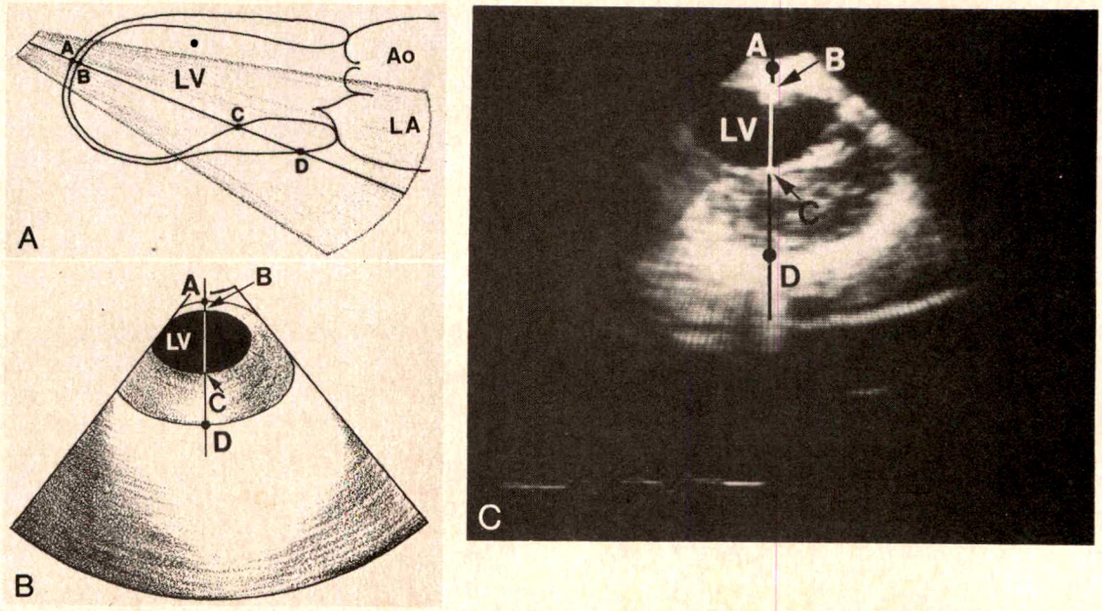

GURE 12. A, diagram depicting an apical long axis view in a patient with an apical aneurysm. An echo plane that could be obtained from the apex also noted. The main axis of this echo plane intersects the aneurysmal epicardium at point A and its endocardium at point B. The apical plane somewhat tangential to the uninvolved inferior wall intersecting the endocardium at point C and epicardium at point D. **B,** diagram of the apical ne echocardiogram diagrammed in **A**. This plane is perpendicular to the aneurysm (A, B) but tangential to the normal inferior wall (C, D). The gential data from the inferior wall simulate a mural thrombus. **C,** still frame two dimensional image of a plane perpendicular to an aneurysmal cal segment but tangential to the normal inferior myocardial wall as depicted in **B**. These tangential data simulate a mural thrombus. Images ained by different sector orientations and acoustic windows can clarify the anatomy of the apex and avoid misinterpretation of tangential data thrombus. Ao = aorta; other abbreviations as in Figures 1 and 3.

raphy. This technique is clinically useful for detecting ft ventricular thrombi and appears more sensitive an angiography. Possible errors from misinterpretaon of spurious intracavitary echoes must be avoided. addition, papillary muscles, muscle trabeculae, ordal structures and tangential left ventricular muscle ust be correctly identified to avoid false positive inpretations.

HOW TO MAKE STRESS TESTING A ONE-PERSON OPERATION.

IRE ANTHRO-METRICS CC-101

Introducing the stress test ystem that only takes one person operate: Anthro-metrics CC-101.

Now stress tests can be dministered by the doctor. Or by technician. Either way, the CC-101 elivers improved data accuracy nd lower cost per patient than ver before possible.

rinted Test Reports

With the CC-101, there's no time st taking notes. Or typing them. ecause at the end of the test, it itomatically summarizes test data r the doctor to review. A printed report provides a complete analysis for the patient's file in a standard 8½" x 11" format.

Improved Accuracy

The CC-101 virtually eliminates artifacts and outside electrical interference. There is automatic time correlation between blood pressure readings, heart rate, S-T segment and test stage. And the CC-101's advanced microprocessor control sets industry standards for accuracy.

Lower Cost per Patient

Anthro-metrics provides physicians with more useful data for less. Less training time. Less time t set the machine before tests. Less personnel to conduct the tests. Even less expensive supply costs.

So you get more tests. For les cost per patient.

Put ANTHRO-METRICS CC-101 to work for you.

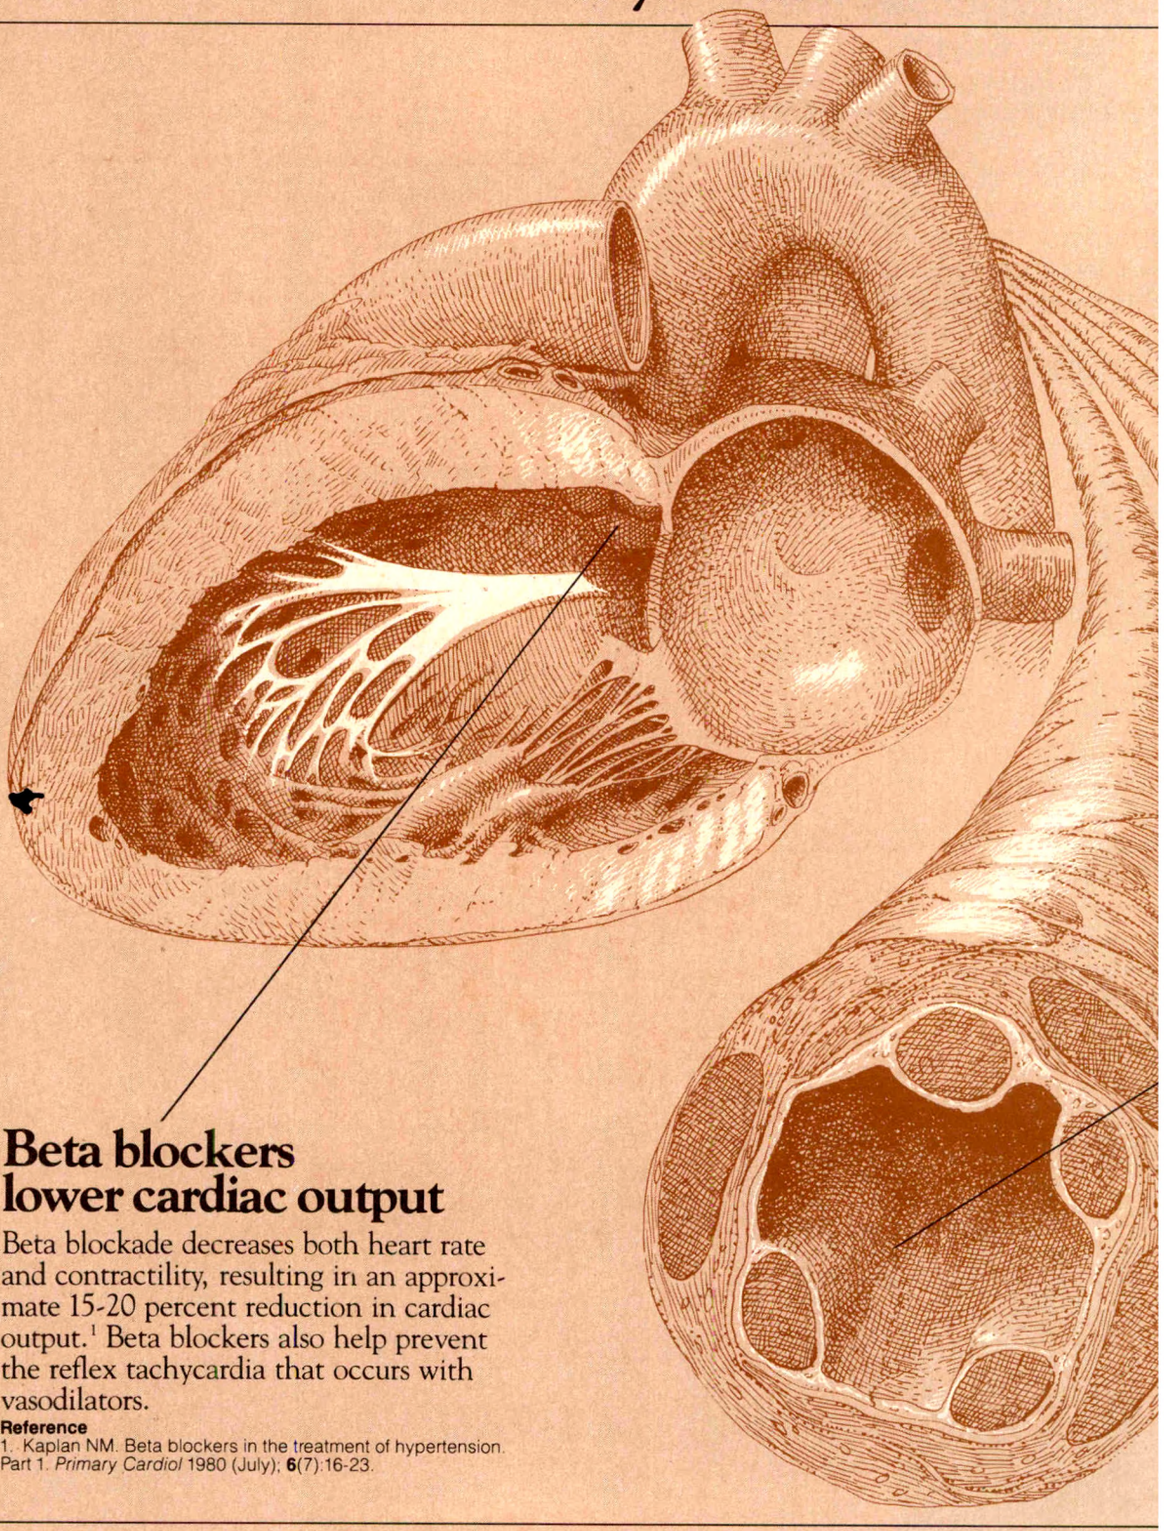
After a diuretic...

Apresoline
hydralazine



Beta blockers lower cardiac output

Beta blockade decreases both heart rate and contractility, resulting in an approximate 15-20 percent reduction in cardiac output.[1] Beta blockers also help prevent the reflex tachycardia that occurs with vasodilators.

Reference

1. Kaplan NM. Beta blockers in the treatment of hypertension. Part 1. *Primary Cardiol* 1980 (July); **6**(7):16-23.

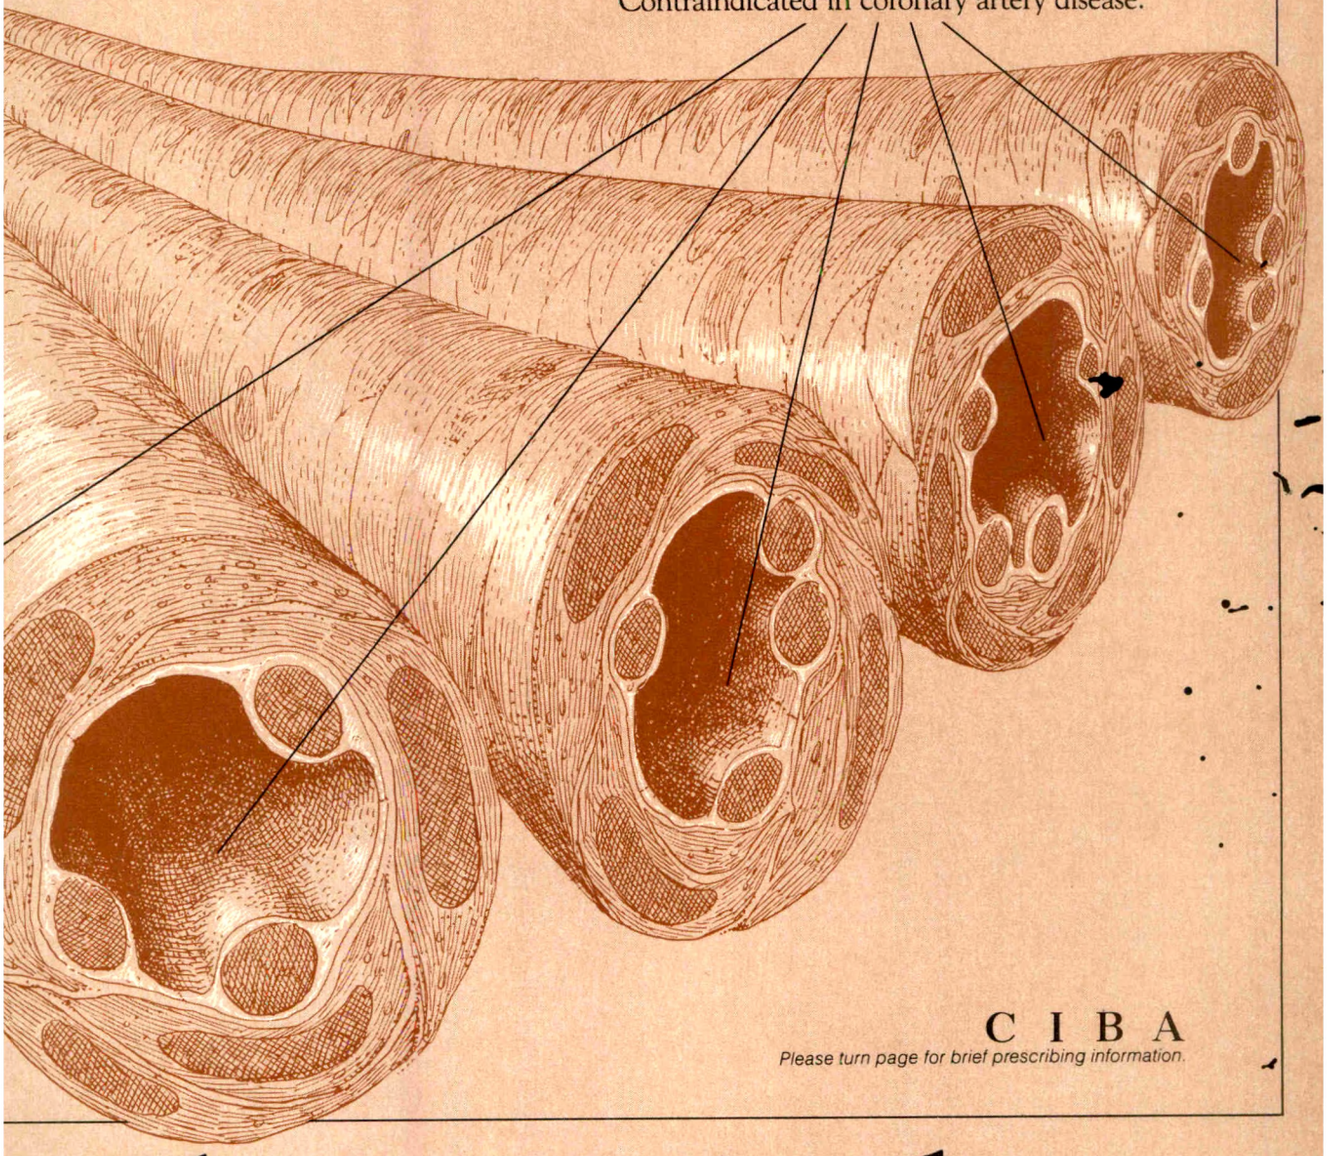
Where today's action is i

& the beta blockers

Apresoline lowers peripheral resistance

By relaxing smooth muscles in the walls of peripheral arterioles—an effect lacking in a beta blocker—Apresoline acts to lower elevated peripheral resistance.

As with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.



CIBA

Please turn page for brief prescribing information.

antihypertensive therapy

presoline® hydrochloride
/dralazine hydrochloride USP

ABLETS

DICATIONS

ssential hypertension, alone or as an adjunct.

ONTRAINDICATIONS

/persensitivity to hydralazine; coronary artery disease; and mitral ilvular rheumatic heart disease.

ARNINGS

/dralazine may produce in a few patients a clinical picture simulating ystemic lupus erythematosus. In such patients hydralazine should be scontinued unless the benefit-to-risk determination requires continued ntihypertensive therapy with this drug. Symptoms and signs usually gress when the drug is discontinued but residua have been detected any years later. Long-term treatment with steroids may be necessary. omplete blood counts, L.E. cell preparations, and antinuclear antibody er determinations are indicated before and periodically during pro- ged therapy with hydralazine even though the patient is asymptomatic. ese studies are also indicated if the patient develops arthralgia, fever, ieart pain, continued malaise or other unexplained signs or symptoms. positive antinuclear antibody titer and/or positive L.E. cell reaction quires that the physician carefully weigh the implications of the test sults against the benefits to be derived from antihypertensive therapy th hydralazine.

se MAO inhibitors with caution in patients receiving hydralazine.

nen other potent parenteral antihypertensive drugs, such as diazoxide, e used in combination with hydralazine, patients should be continu- sly observed for several hours for any excessive fall in blood pressure. ofound hypotensive episodes may occur when diazoxide injection and presoline (hydralazine hydrochloride) are used concomitantly.

sage in Pregnancy

imal studies indicate that hydralazine is teratogenic in mice, possibly rabbits, and not in rats. Teratogenic effects observed were cleft palate d malformations of facial and cranial bones. Although clinical perience does not include any positive evidence of adverse effects the human fetus, hydralazine should not be used during pregnancy less the expected benefit clearly justifies the potential risk to the fetus.

ECAUTIONS

/ocardial stimulation produced by Apresoline can cause anginal acks and ECG changes of myocardial ischemia. The drug has been plicated in the production of myocardial infarction. It must, therefore, used with caution in patients with suspected coronary artery disease. e "hyperdynamic" circulation caused by Apresoline may accentuate ecific cardiovascular inadequacies. An example is that Apresoline ay increase pulmonary artery pressure in patients with mitral valvular ease. The drug may reduce the pressor responses to epinephrine. stural hypotension may result from Apresoline, but is less common an with ganglionic blocking agents. Use with caution in patients with rebral vascular accidents.

hypertensive patients with normal kidneys who are treated with resoline, there is evidence of increased renal blood flow and a intenance of glomerular filtration rate. In some instances improved al function has been noted where control values were below normal or to Apresoline administration. However, as with any antihypertensive ent, Apresoline should be used with caution in patients with advanced al damage.

ripheral neuritis, evidenced by paresthesias, numbness, and tingling, s been observed. Published evidence suggests an antipyridoxine ect and the addition of pyridoxine to the regimen if symptoms develop. od dyscrasias, consisting of reduction in hemoglobin and red cell nt, leukopenia, agranulocytosis, and purpura, have been reported. If h abnormalities develop, discontinue therapy. Periodic blood counts advised during prolonged therapy.

e Apresoline tablets (10 and 100 mg) contain FD&C Yellow No. 5 rtrazine) which may cause allergic-type reactions (including bronchial hma) in certain susceptible individuals. Although the overall inci- nce of FD&C Yellow No. 5 (tartrazine) sensitivity in the general pulation is low, it is frequently seen in patients who also have aspirin persensitivity.

VERSE REACTIONS

verse reactions with Apresoline are usually reversible when dosage educed. However, in some cases it may be necessary to discontinue drug.

mmon: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; hycardia; angina pectoris.

ss frequent: Nasal congestion; flushing ; lacrimation; conjunctivitis; ripheral neuritis, evidenced by paresthesias, numbness, and tingling; ema; dizziness; tremors; muscle cramps; psychotic reactions charac- zed by depression, disorientation, or anxiety; hypersensitivity cluding rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, d, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; ralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, con- ting of reduction in hemoglobin and red cell count, leukopenia, agran- cytosis, and purpura; hypotension; paradoxical pressor response.

SAGE AND ADMINISTRATION

iate therapy in gradually increasing dosages; adjust according to ividual response. Start with 10 mg 4 times daily for the first 2 to ays, increase to 25 mg 4 times daily for balance of first week. For cond and subsequent weeks, increase dosage to 50 mg 4 times daily. maintenance, adjust dosage to lowest effective levels.

incidence of toxic reactions, particularly the L.E. cell syndrome, igh in the group of patients receiving large doses of Apresoline. few resistant patients, up to 300 mg Apresoline daily may be uired for a significant antihypertensive effect. In such cases, a lower sage of Apresoline combined with a thiazide, reserpine, or both may considered. However, when combining therapy, individual titration is ential to insure the lowest possible therapeutic dose of each drug.

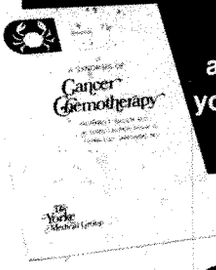
How to Keep Up with Drug Interaction in Cancer Chemotherapy



Three authorities from a leading medical center show you how to use the most current chemotherapeutic agents

A SYNOPSIS OF

Cancer Chemotherapy

At last a way to keep up with the bewildering proliferation of new chemotherapeutic drugs which have come into use relatively recently. This recently published guide will be valuable to every hospital, and every oncology specialist, general internist, clinical pharmacist, and nurse oncologist.

A SYNOPSIS OF CANCER CHEMOTHERAPY is a concise, readily understandable "how to" manual. Developed originally for staff use at The New York Hospital-Cornell Medical Center, the concept proved so successful it was decided to make it available to other professionals. The new users of the SYNOPSIS have the advantage of a proven, time-tested learning system. It is written in a unique, compact work-book style to keep reading time to a minimum.

The reader can quickly find the following for both commercially available and investigational drugs:

- Structure
- Mechanism of Action
- Pharmacokinetics
- Toxicity
- Therapy
- Availability

The chemotherapeutic agents in the main listing section cover these categories:

- Alkylating Agents
- Antimetabolites
- Mitotic Inhibitors
- Antibiotics
- Miscellaneous (includes such drugs as Mithramycin, Mitotane, etc.)

RICHARD T. SILVER, MD, F.A.C.P., F.A.B.C.O.
Chief, Oncology Service, Div. Hematology-Oncology, Clinical Professor of Medicine, Cornell University Medical College, Attending Physician, New York Hospital, Exec. Officer, Cancer & Leukemia Group B.

R. DAVID LAUPER, Pharm. D.
Asst. Director for Education and Information, Pharmacy Dept., New York Hospital-Cornell Medical Center.

CHARLES I. JAROWSKI, MD
Instructor in Medicine, Cornell University Medical College, Senior Chemotherapy Fellow, Div. of Hematology-Oncology, The New York Hospital.

Use it for 30 days—FREE

Refer to it for chemotherapeutic drug information for a full month. Then keep the book only if you want it for permanent reference. Otherwise simply return it and owe nothing. You have nothing to lose and a whole world of valuable life-saving knowledge to gain. Order right now!

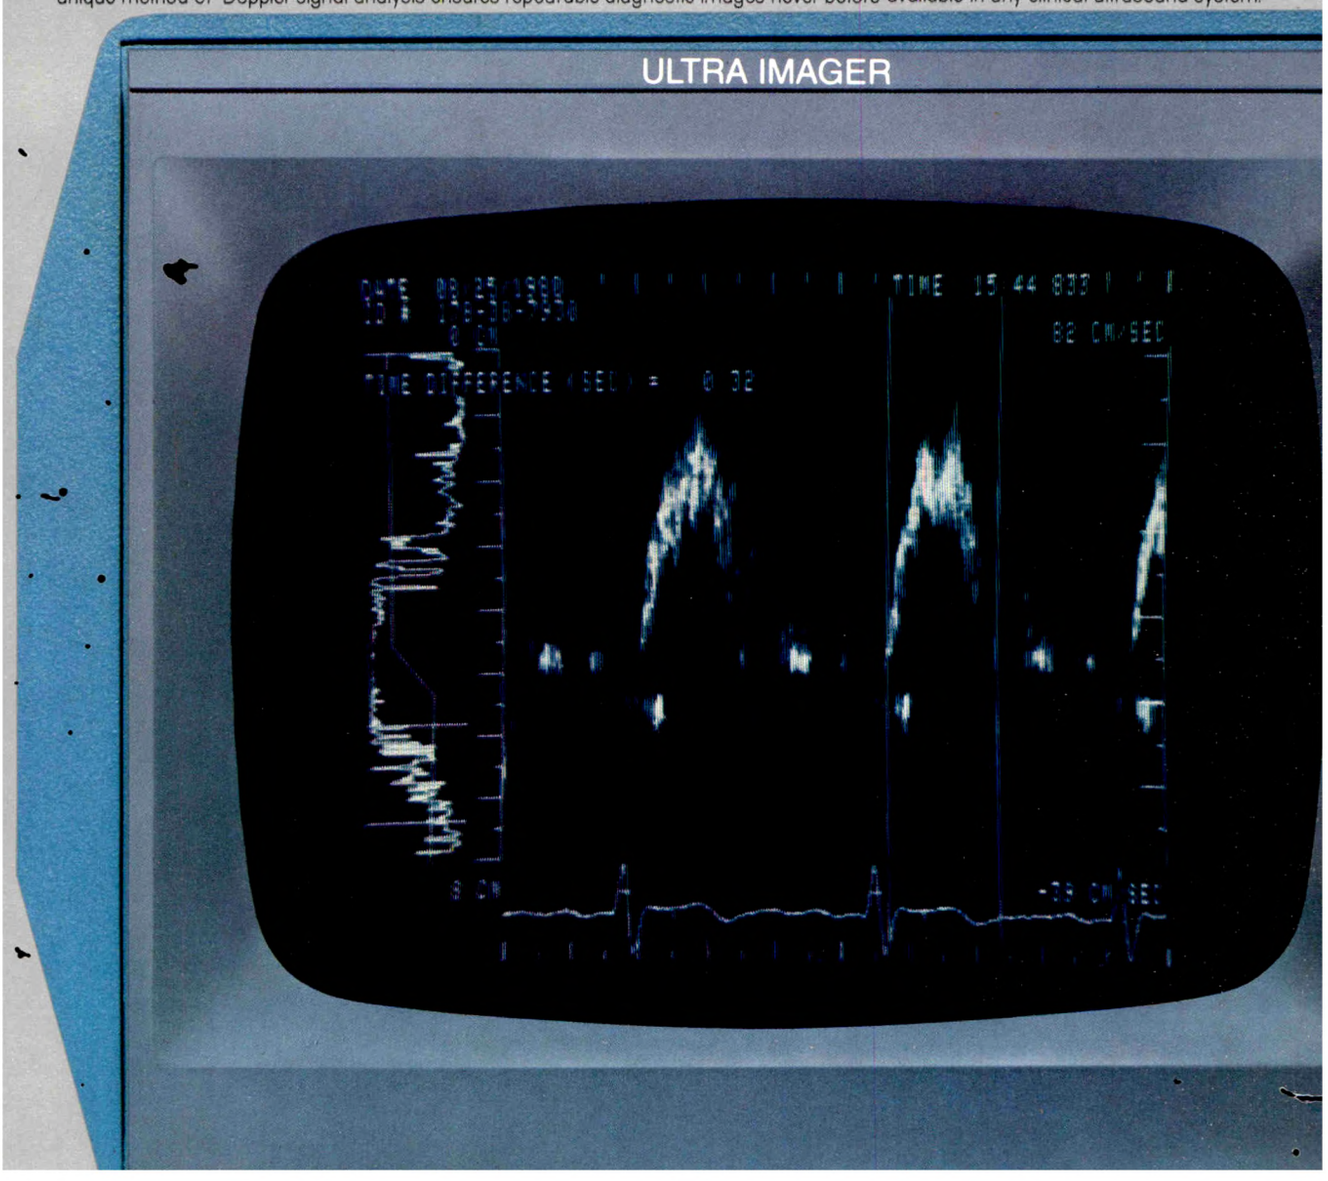
E for M/Honeywell announces the first major advance of the 1980's in echocardiography....

Ultra Imager

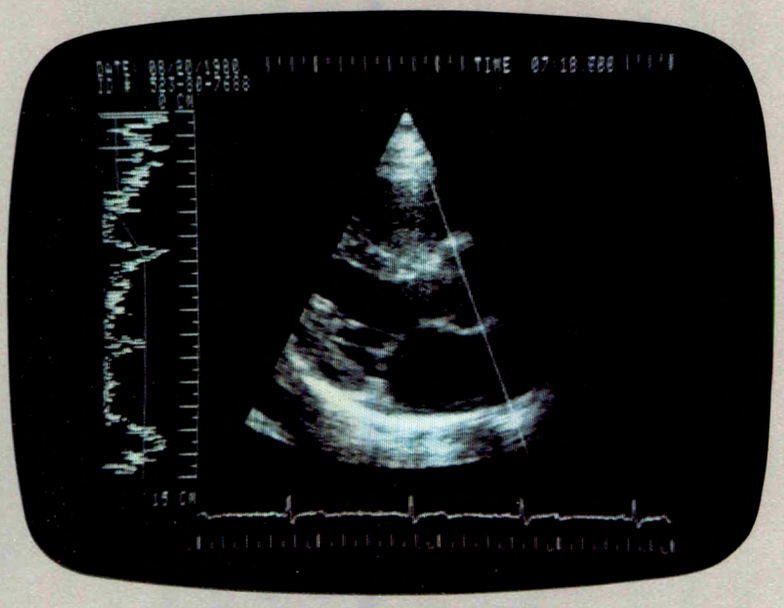
The only integrated digital echocardiography system with all <u>three</u> major modalities for complete ultrasound diagnosis:

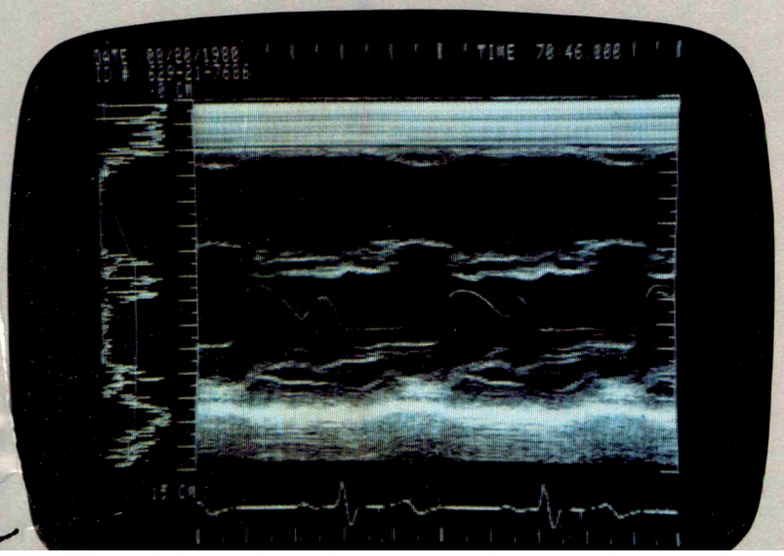
- **Repeatable Pulsed Doppler**
- **2D Real-time**
- **M-mode**

This pulsed Doppler display is a precise, quantitative representation of a spectrum of blood velocities in the pulmonary artery. The Ultra Imager's unique method of Doppler signal analysis ensures repeatable diagnostic images never before available in any clinical ultrasound system.



E FOR M / Honeywell





Three complementary imaging modalities:

- Pulsed Doppler
- Real-time
- M-mode

On a single video display, the Ultra Imager presents enhanced 2D sector scans, M-mode images or pulsed Doppler data. These three imaging modalities are combined in ways that yield more diagnostic information than ever before. For example, you can change instantly from one mode to another by pressing a button—or use a cursor on a 2D image to determine the placement of an M-mode recording.

The Ultra Imager's multiprocessor system puts cursors and image controls at your fingertips. It also places graphics and alphanumeric messages on the screen to make every examination faster and easier.

The Ultra Imager also provides diagnostic quality physiological signal conditioning. Every system includes an ECG channel and can accommodate optional pulse/phono and respiration channels.

Cost-effectiveness built into the Ultra Imager System

The Ultra Imager offers many cost-effective features that enhance its value to cardiology practice. The mechanical sector scan was selected for the system because it offers superior performance in 2D/Doppler imaging at lower cost. In addition, it will permit ready adaptation to future transducer technologies.

Ease of maintenance is again achieved, along with greater electronic stability, by comprehensive digital processing throughout the system. Integrated design of the Ultra Imager avoids the cabling connections and duplicated components associated with the "stacked box" approach.

The system's digital scan converter (image memory) provides you with non-fade displays and gives you instantaneous freeze-frames in any mode without flickering or fading. These advanced display capabilities facilitate diagnostic review and the measurement and recording of scan data.

The unique Auto-Test feature of the Ultra Imager allows the system to test itself for failures. If a failure exists, an appropriate indicator light signals the source of the failure. This simplifies servicing of the instrument.

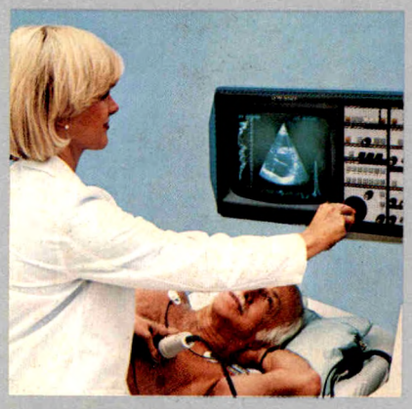
Human engineered with unique operator convenience features

Through careful attention to human engineering details, we have made a sophisticated imaging system easy to operate.

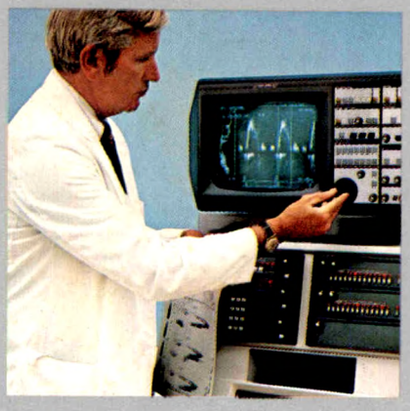
For instance, both the monitor and primary control panel are on a movable gantry that can be positioned near the patient for ease of use and viewing. This makes system controls conveniently accessible to the operator while at the patient's bedside.

The Ultra Imager also includes an audio-visual self-teaching feature which employs the system's videotape recorder to play training programs produced by E for M/ Honeywell. This convenient feature makes staff training a much simpler procedure.

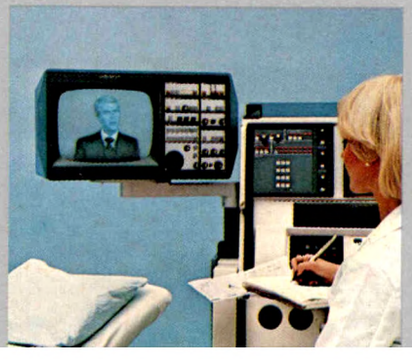
For operator convenience, all displays can be viewed easily even in a daylit room. There is also built-in storage space for gels, tissues, paper and other supplies. Because the cart is compact and easily maneuvered, it can be moved wherever needed.



Operator can position the transducer and be within convenient reach of all necessary scan controls.



Cardiologist can perform off-line data analysis while listening to voice annotations recorded by the operator.



Audiovisual self-teaching feature facilitates training of new personnel.

A versatile imaging system that offers more diagnostic information and greater clinical utility.

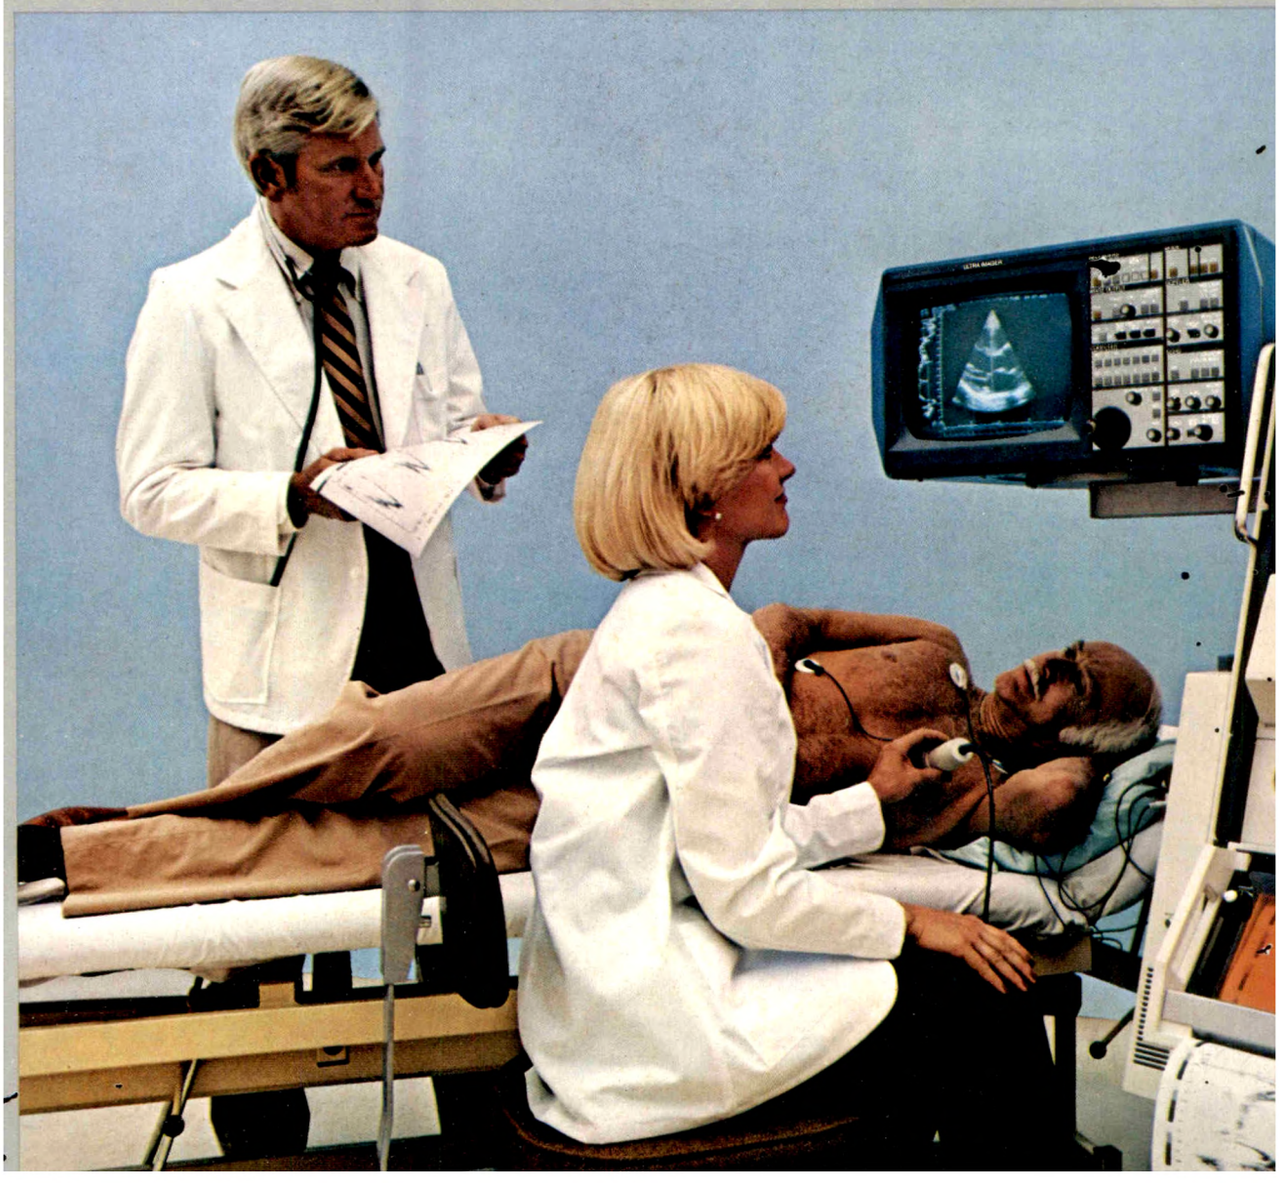
Today the key to diagnostic value in an echocardiography system is the availability of accurate and repeatable pulsed Doppler images. The Ultra Imager offers you this plus the complementary imaging capabilities you need to perform cardiac examinations.

Using a sophisticated spectral analysis technique called Fast Fourier Transform (FFT) the Ultra Imager can process Doppler blood velocity data in real time without the need for an operator to calibrate gain and threshold settings. This makes quantitation of blood flow patterns and flow rates throughout the heart a much simpler clinical procedure.

The Ultra Imager's built-in versatility is made possible by a unique, dedicated array processor designed to handle the high-speed computations required for repeatable Doppler imaging. The computing power of this separate processor makes it possible to combine accurate blood velocities with 2D imaging data to provide the essential measurements for determining stroke volume and cardiac output. The Ultra Imager is the only 2D/Doppler System available offering this level of diagnostic versatility.

Honeywell's new LS-8 recorder is a standard system feature. It allows you to make a hard copy of the display with full gray scale reproduction and high resolution. You can select page print or strip chart modes and get crisp, black-on-white records with immediate dry processing.

High quality videotaped images are formatted to allow off-line data analysis on playback images. This storage feature allows both physician and operator to conduct diagnostic reviews when it is most convenient.



The E for M/Honeywell Commitment

E for M/Honeywell has a special commitment to cardiology. Because we've worked with you for over 30 years, we know the kind of service and performance you demand from a medical instrument company. Over the years, we've developed a professional rapport which has led to the development and manufacture of many of the best-engineered, high performance instruments in the healthcare field. The Ultra Imager is one more example of this continuing commitment to excellence.

Service

The Ultra Imager is supported in the field by our own specially trained ultrasound service technicians. Because there are over 40 service locations in the U.S. alone, E for M/Honeywell service is fast and responsive. A toll-free number connected to the Ultra Imager Support Center makes service available 24 hours a day.

The Ultra Imager's Auto-Test feature further minimizes downtime by pinpointing any failures in the system. Now if a service call is needed the technician knows which parts are required to repair the system on-site. In addition, the Repair/Exchange program provides immediate replacement parts for your service technician with the lowest possible board repair cost through the use of Automatic Test Equipment at the factory.

Quality Assurance

The Ultra Imager was designed with reliability and ease of maintenance in mind. "MIL-Spec" reliability analyses were used to evaluate every aspect of the system design. Each subassembly has been thoroughly tested individually and as part of the complete system. And every completed unit is subjected to rigorous temperature cycling so that any marginal components can be replaced in the factory. This means that the system we install for you is in optimum working order.

Therapy of Coronary Vasoconstriction in Patients With Coronary Artery Disease

STEPHEN GUNTHER, MD
JAMES E. MULLER, MD
GILBERT H. MUDGE, Jr., MD
WILLIAM GROSSMAN, MD, FACC

Boston, Massachusetts

Patients with obstructive coronary artery disease and stable, exertional angina respond to the alpha adrenergic stimulus of the cold pressor test with an inappropriate increase in coronary vascular resistance. The clinical significance of this abnormal response and its possible role in the pathogenesis of ischemic heart disease are discussed.

Comparison of the anti-anginal agents currently in use or undergoing investigation suggests that the calcium antagonists may be the most effective therapy for coronary vasoconstriction. Nifedipine, 10 mg buccally, successfully prevented the increase in coronary vascular resistance during the cold pressor test in 10 of 10 patients, whereas the response in placebo-treated patients was unaltered. This dose of nifedipine was without effect on systemic hemodynamics or myocardial oxygen consumption, suggesting a selective antivasoconstrictor effect on the coronary vasculature.

The rational therapy of ischemic heart disease is dependent on our understanding of the pathogenetic mechanisms that result in angina pectoris and myocardial infarction. The concept that myocardial perfusion is limited only by the fixed, obstructive lesions of coronary artery disease is now giving way to the growing recognition that abnormal coronary vasoconstriction can also, in some instances, restrict blood flow and contribute to myocardial ischemia.[1] The adverse effects of altered coronary tone have been most dramatically demonstrated as the coronary vasospasm of Prinzmetal's angina,[2,3] but similar mechanisms have also been implicated as a cause of angina at rest and myocardial infarction[7,8] in some patients. However, it is not necessary to invoke coronary vasoconstriction to account for the symptoms of the larger group of patients with obstructive coronary disease and stable, exertional angina.[9] A transient increase in myocardial oxygen demand, beyond the oxygen-delivering capabilities of the stenotic coronary arteries, is sufficient to cause ischemia in such patients. Nevertheless, a variety of evidence from recent investigations[10] suggests that even in these patients, coronary vasoconstriction can occur and, by restricting myocardial blood flow during periods of enhanced metabolic demand, contribute to the development of myocardial ischemia.

Before the implications of these concepts can be discussed, it is necessary to address three questions: (1) What is the evidence that coronary vasoconstriction occurs in patients with stable, exertional angina? (2) What is the clinical significance of coronary vasoconstriction? (3) What is the appropriate therapy for this disorder?

Demonstration of Coronary Vasoconstriction in Patients With Exertional Angina

The human coronary circulation is subject to metabolic, mechanical and neurogenic influences.[11] In patients with atherosclerotic heart disease, the presence of stenotic lesions in epicardial vessels imposes additional hemodynamic restraints on the vasodilatory response to metabolic stimuli.[12] The strong correlation of coronary blood flow and myocardial

oxygen consumption[13] and the limited effects of sympathetic nerve stimulation on coronary tone in anesthetized animals[14] led to the earlier conclusion that coronary blood flow was predominantly controlled by locally released myocardial metabolites.[15] However, it has become apparent from more recent studies in conscious animals and man that alpha adrenergic vasoconstrictor mechanisms exert a significant influence on coronary vascular tone.[16–18] Reflex reduction in this alpha adrenergic tone during carotid sinus nerve stimulation results in coronary vasodilation[16]; conversely, alpha adrenergic activation during exercise and other physiologic stimuli cause coronary vasoconstriction despite increased myocardial metabolic demand.[19,20]

Effects of neurogenic stimulation by the cold pressor test: To evaluate the effects of neurogenic stimulation on the human coronary circulation, we have challenged patients with the cold pressor test, a stimulus that causes peripheral vasoconstriction mediated by alpha adrenergic receptors, while measuring coronary sinus blood flow by the thermodilution technique.[21] In subjects with normal coronary arteries, the cold pressor test produced an increase in mean arterial pressure, and a parallel increase in coronary sinus blood flow. Therefore, coronary vascular resistance remained unchanged (Fig. 1). In patients with coronary artery disease, however, the increase in blood pressure was not accompanied by an increase in coronary sinus flow. Coronary vascular resistance in these patients was significantly increased.

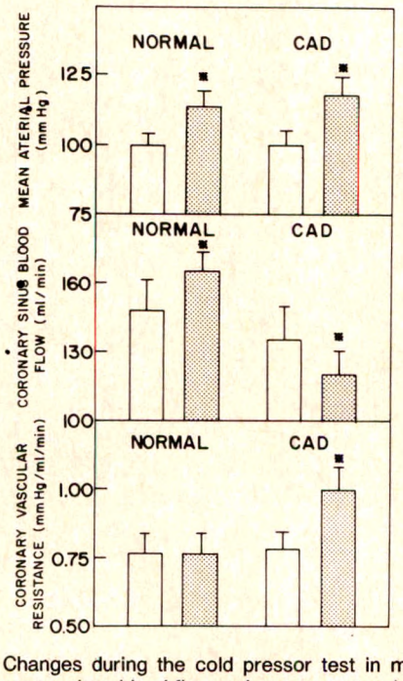

FIGURE 1. Changes during the cold pressor test in mean arterial pressure, coronary sinus blood flow and coronary vascular resistance in 12 normal subjects and 12 patients with coronary artery disease (CAD). **Open bars** = values at rest; **stippled bars** = values during cold pressor test. **Brackets** represent 1 standard deviation. (* = $p < 0.05$ compared with resting values for same group.)

The occurrence of coronary vasoconstriction during the cold pressor test appears to be a common feature of obstructive coronary artery disease and has been demonstrated in more than 60 patients studied in our laboratory. All of these patients had stable, exertional angina with no clinical symptoms or electrocardiographic evidence of Prinzmetal's angina.

Clinical Significance of Coronary Vasoconstriction

The demonstration of abnormal coronary vasoconstriction in patients with coronary artery disease would be of minor interest if the vasoconstriction caused no significant hemodynamic changes or symptoms. However, as shown in Table I, angina pectoris and other adverse effects occur during the cold pressor test in a sizable proportion of patients subjected to this stimulus.

Angina: Angina developed during the cold pressor test in approximately 30 percent of patients. Although 12 lead electrocardiograms were not routinely obtained, the chest pain was described by all patients as typical of that occurring during exertion, and subsided in each patient only after cessation of the cold pressor test. Of interest is the development of angina in these patients at a time when myocardial oxygen consumption, estimated by the heart rate-blood pressure product, became only slightly elevated, that is, by 10 to 20 percent. In the patients in this group who subsequently underwent rapid atrial pacing in the absence of the cold pressor test, the rate-pressure product could be elevated to much higher levels, that is, to 90 to 110 percent above the control level before angina developed.[22] These data suggest that the coronary vasoconstrictor response can effectively lower the "anginal threshold" by restricting myocardial blood flow.

Myocardial metabolism: Objective evidence of myocardial ischemia, as judged by a conversion of the arterial-coronary sinus lactate difference from positive to negative,[23] that is, lactate production, was demonstrated during the cold pressor test in 4 of 15 patients in whom these measurements were made. A less dramatic indication of impaired myocardial perfusion, that is, widening of the arterial-coronary sinus oxygen dif-

TABLE I

Incidence of Adverse Effects of Coronary Vasoconstriction During the Cold Pressor Test

Event	Patients Affected	
	n	%
Angina	12 of 39	31
Negative myocardial lactate uptake	4 of 15	27
Widened arterial-coronary sinus oxygen difference	14 of 15	93
New abnormalities in regional myocardial blood flow	9 of 10	90
Global decrease in left ventricular ejection fraction	10 of 10	100

ference (from 11.5 ± 0.3 to 12.3 ± 0.3 ml/100 ml, $p < 0.05$[24]), was observed in 14 of the 15 patients. Because the coronary sinus catheter samples blood from multiple areas of left ventricular myocardium, it is possible that greater changes in oxygen extraction occurred in some regions, but were masked by normally oxygenated venous blood from well perfused regions.

Regional myocardial blood flow: Preliminary studies measuring regional myocardial flow during the cold pressor test by the xenon-^{133} washout technique[25] have yielded two important results: (1) The abnormal increase in coronary vascular resistance measured by thermodilution in patients with coronary artery disease has been confirmed by an entirely independent method of quantifying myocardial blood flow; and (2) in patients with coronary disease, blood flow was unchanged, or actually decreased, only in those regions of myocardium supplied by diseased coronary arteries; blood flow to regions supplied by normal vessels increased appropriately, as it did in all regions in normal subjects. Abnormal coronary vasoconstriction, therefore, appears to occur only in the distribution of diseased vessels and is not a generalized vascular disorder.

Left ventricular function: Radionuclide ventriculography was used to assess noninvasively changes in left ventricular function during the cold pressor test in 10 patients. Global ventricular function (left ventricular ejection fraction) decreased slightly, but significantly (5 to 10 percent) in all patients. A new abnormality of segmental wall motion could be identified in only one patient. It is not yet known whether the decrease in ejection fraction is specifically the result of coronary vasoconstriction or the result of increased afterload, or of both mechanisms.

Coronary vasoconstriction during exercise: Although our studies have used the cold pressor test as a provocative stimulus to demonstrate coronary vasoconstriction in patients with coronary artery disease, it is possible that adrenergic stimulation during other forms of stress, such as exercise, may also activate neurogenically mediated vasoconstriction.[19,20] Frank spasm of epicardial arteries during exercise has been documented by coronary arteriography in some patients with exertional angina.[26] More subtle forms of vasoconstriction, detectable only by direct measurements of coronary blood flow, may be more common. The presence of even normal alpha adrenergic tone in the coronary circulation during exercise could be deleterious in patients whose vasodilatory reserve is already diminished by obstructive coronary lesions. Further studies are clearly needed to clarify the role of coronary vasoconstriction in the pathogenesis of exercise-induced ischemia.

Therapy of Coronary Vasoconstriction

The recognition of a vasoconstrictive component in various forms of ischemic heart disease has renewed interest in alternative forms of therapy for this disorder. It is appropriate to review our experience with representative agents from each of these groups in relation to coronary vasoconstriction.

Propranolol: The beta adrenergic blocking agent propranolol is obviously effective in the treatment of myocardial ischemia due to transiently increased myocardial oxygen demand. It appears to be considerably less useful in the treatment of vasospastic (Prinzmetal's) angina.[27,28] Propranolol can secondarily increase coronary vascular resistance by reducing myocardial oxygen consumption[29] and, theoretically, by inhibiting vasodilatory mechanisms mediated by $beta_2$ receptors, could potentiate the coronary response to vasoconstrictor stimuli.[30] Studies reporting a worsening of symptoms in some patients with variant angina during propranolol therapy support such a hypothesis.[31,32]

To assess the effects of propranolol on the abnormal coronary vasoconstriction of patients with coronary artery disease, we compared the cold pressor test responses of patients receiving their usual doses of propranolol during the test to those of a similar group of patients who had discontinued propranolol therapy at least 8 hours before catheterization[22] (Table II). There were no significant differences in the hemodynamic or coronary vascular responses of the two groups. The patients with normal coronary arteries had a normal response; the patients with coronary artery disease had an abnormal vasoconstrictor response. These data indicate that the vasoconstrictor response is not an artifact caused by beta adrenergic blockade, but they also suggest that vasoconstriction is not prevented by propranolol. Sequential cold pressor tests in the same patient, before and after acute administration of propranolol, will be needed to confirm the latter suggestion.

Nitroglycerin and long-acting nitrates: Nitrates, of course, are potent vasodilators, and administration of sublingual or intravenous nitroglycerin is effective in preventing or relieving coronary vasospasm. The prophylactic effectiveness of long-acting nitrates is less certain. Less than half of a large series of patients with Prinzmetal's angina manifested even partial improvement with long-acting nitrate therapy.[28] Maseri et al.[8] reported that 37 of 87 consecutive patients admitted with vasospastic angina had an acute myocardial infarction within 1 month despite treatment with large

TABLE II

Cold Pressor Test Responses With (+) and Without (−) Propranolol

	ΔBP	ΔCSBF	ΔCVR
Normal subjects			
+ propranolol (n = 12)	+14 ± 1%	+15 ± 4%	0 ± 2%
− propranolol (n = 14)	+17 ± 2%	+26 ± 3%	−3 ± 1%
Patients with CAD			
+ propranolol (n = 12)	+18 ± 3%	−10 ± 3%	+27 ± 3%
− propranolol (n = 13)	+20 ± 2%	−5 ± 1%	+25 ± 3%

Values expressed as mean values ± standard error of the mean.
CAD = coronary artery disease; ΔBP = % change in mean arterial pressure during the cold pressor test; ΔCSBF = % change in coronary sinus blood flow; ΔCVR = % change in coronary vascular resistance.

loses of nitrates. The coronary vasoconstrictor response o the cold pressor test likewise appears to be unaffected y long-acting nitrates. The responses in patients naintained on nitrate therapy were, as in the case of ropranolol, indistinguishable from those in whom nirate therapy had been withdrawn. These findings may e explained by the relative specificity of clinically seful doses of orally administered nitrates for venous apacitance vessels rather than arterial resistance vesels.[33] Unfavorable pharmacokinetics of oral nitrates ıay also play a role, since a recent report[34] suggests that ntinuous intravenous infusion of nitrates may be ective in preventing coronary vasospasm. Such therapy obviously impractical for patients with chronic, stable ngina.

Alpha adrenergic antagonists (phentolamine): he third group of agents, the alpha adrenergic antagnists, should theoretically be effective in preventing he abnormal coronary vasoconstrictor response because he cold pressor test is at least partly mediated by acivation of alpha adrenergic vascular receptors. Coroary vasoconstriction during the cold pressor test *can* e blocked by intravenous phentolamine (Fig. 2); owever, the effect is nonspecific because the systemic ressor response is also blocked. This lack of specificity nderlies the difficulties in the clinical use of an alpha drenergic antagonist. It is difficult to maintain adeuate alpha adrenergic blockade in ambulatory patients ithout adverse effects, such as postural hypotension. n patients also receiving larger doses of a beta adrenrgic antagonist, the result is comparable to chemical ympathectomy and not well tolerated.

Calcium antagonists (nifedipine): The final group f agents, the calcium antagonists, is composed of sevral vasodilator drugs with an apparently unique ıechanism of action. Unlike nitrates and other vasoilators, they can prevent smooth muscle contraction y inhibiting the slow inward current of calcium during

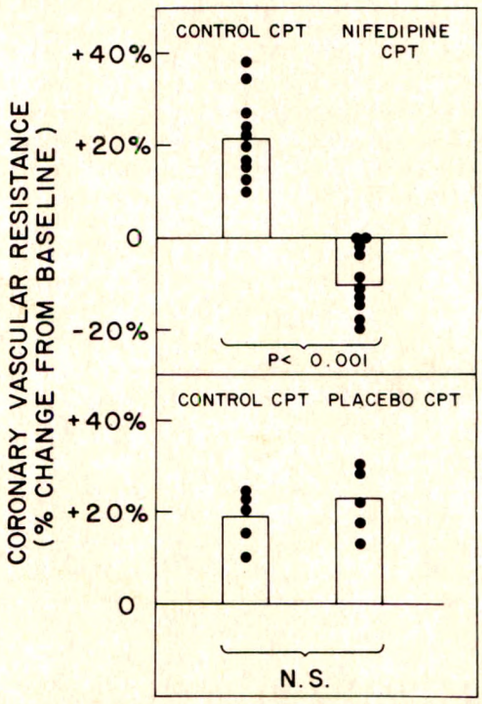

FIGURE 3. Changes in coronary vascular resistance during a cold pressor test (CPT) in 10 patients before and after administration of nifedipine (**upper panel**) and in 5 patients before and after placebo (**lower panel**).

depolarization that is responsible for excitation-contraction coupling.[35] Although used for several years in Europe and Japan in the treatment of classic exertional angina,[36] they have recently become of great interest because of their antispasmodic properties.[37]

The favorable experience with one of these drugs, nifedipine, in preventing the vasospasm of Prinzmetal's angina,[27,28] prompted us to investigate its usefulness in preventing the coronary vasoconstrictor response of patients with coronary artery disease and exertional angina. Fifteen patients underwent a cold pressor before and after the administration of nifedipine (10 mg buccal) or placebo.[24] Figure 3 illustrates that nifedipine

TABLE III

successfully prevented coronary vasoconstriction in each of the 10 patients tested, while the response in the 5 patients given placebo was essentially unchanged. Four of the patients who subsequently received nifedipine had angina during the control cold pressor test; none of these patients were symptomatic during the nifedipine cold pressor test. Nifedipine, at the dose used, prevented abnormal coronary vasoconstriction without affecting systemic hemodynamics, either at rest or during the cold pressor test (Table III). Because the changes in arterial pressure, left ventricular end-diastolic pressure and myocardial oxygen consumption were comparable during the two cold pressor tests, nifedipine appeared to exert a selective, antivasoconstrictor effect on the coronary circulation. At this dosage, nifedipine was well tolerated without side effects by all patients.

Conclusions

Coronary vasoconstriction has been demonstrated in many types of ischemic heart disease. Coronary arterial vasospasm plays a pathogenetic role in Prinzmetal's angina, and probably in some forms of unstable angina and myocardial infarction as well. Milder, but clinically significant degrees of coronary vasoconstriction occur in patients with stable, exertional angina during the stimulus of the cold pressor test. Studies in experimental animals and in patients with coronary artery disease indicate that such vasoconstrictor mechanisms can effectively restrict coronary blood flow when myocardial demand is increased, and thus may play a contributory role in the development of ischemia. Of the anti-anginal drugs, calcium antagonists appear to be the most effective in preventing coronary vasoconstriction.

Nifedipine in the Treatment of Unstable Angina, Coronary Spasm and Myocardial Ischemia

PAUL G. HUGENHOLTZ, MD, FACC
HERMAN R. MICHELS, MD
PATRICK W. SERRUYS, MD
RON W. BROWER, PhD

Rotterdam, The Netherlands

The effects of nifedipine, a potent calcium antagonist, were studied in patients with unstable angina, coronary spasm and myocardial ischemia. Data from two separate groups of patients studied in the cardiac catheterization laboratory indicate that intracoronary injection of nifedipine promptly reversed coronary spasm—whether provoked or spontaneous—in five of six patients. In other patients, direct intracoronary injection of the drug was compared with intravenous administration. After intracoronary injection, local mechanical cardiac action virtually ceased, and the ventricular wall became thinner during systole. Thus, a specific inhibitory action on contractile energy expenditure could be demonstrated in the presence of increased coronary flow. This "oxygen-sparing" effect was tested in a group of 31 patients with symptomatic unstable angina whose pain at rest, with ST-T changes, had not responded to 8 hours of treatment with maximal beta adrenergic blockade, nitrates and bed rest. The addition of 6 × 10 mg of nifedipine rendered 27 of these patients asymptomatic within 1.5 hours. In the four patients who did not respond, coronary arteriography demonstrated severely stenotic lesions. Two of the four patients subsequently responded to intraaortic balloon pumping and bypass surgery; one patient had a myocardial infarction and one who had a 90 percent reduction in the diameter of the left main coronary artery, died.

It is concluded that nifedipine should be added to beta adrenergic blockade therapy if the latter does not appear to be immediately effective. This combination has not been shown to cause any hemodynamic deterioration, and only a minority of the patients treated sustained a myocardial infarction during the first 3 months of follow-up. The use of nifedipine in unstable angina deserves further clinical evaluation.

The concept that coronary vasospasm is one cause of angina pectoris and myocardial infarction has recently been rediscovered, almost a century after the original descriptions by Latham.[1] In fact, in the past few years, several investigators[2–7] have brought about a shift in attitude concerning the pathophysiologic derangements underlying myocardial infarction. It is now accepted that temporary obliteration of coronary blood flow due to increased vessel wall tone, even in the absence of fixed coronary arterial obstruction and stenosis, can lead to myocardial infarction. Most likely, intermittent and fixed coronary stenosis act in combination; that is, increased vasomotility of a major vessel around a fixed obstruction causes the critical reduction in flow that leads to irreversible ischemia. To what extent platelet aggregates and disturbances in prostaglandin metabolism play a role is as yet unclear, but their effects may well be additive.

Such a view opens new avenues for treatment because, if coronary spasm or increased vascular tone can be recognized, timely relief of the condition should reverse the process of impending infarction. Our cur-

rent study relates to several experiences that provide a partial answer to the potential efficacy of nifedipine in this scheme of events. First, nifedipine's powerful action as a calcium antagonist leads to vessel dilation, which has proved effective in classic Prinzmetal's angina in which spasm is known to be the main causative mechanism. Direct intracoronary injection of nifedipine has been observed to lead to prompt restoration of the normal caliber of a totally occluded vessel.

However, other actions of nifedipine may make this drug equally attractive for the treatment of patients with unstable angina pectoris. In our laboratory, measurements of left ventricular function, both in pigs and in human subjects, have shown that local mechanical contraction ceases for up to 5 minutes when nifedipine is injected into the coronary artery supplying the ischemic cardiac muscle. In patients with unstable angina, the best protective action for ischemic cells might be provided if coronary flow could be increased and local consumption of oxygen simultaneously decreased, while electrical activation continued normally.

To test these hypotheses, we studied a group of patients admitted to the coronary care unit with angina pectoris at rest and transient S-T segment or T wave changes but without evidence of acute myocardial infarction, such as abnormal enzyme release and development of Q waves. At our center, this high risk group of patients with unstable angina is routinely managed with bed rest and administration of oxygen, sedatives, long-acting nitrates and beta adrenergic blocking agents. The therapeutic objective is to return the patient with signs of myocardial ischemia to a stable and asymptomatic state, thereby preventing infarction. In our hands, this regimen has not proved successful in all patients. In fact, until recently it was our policy to proceed to emergency coronary bypass surgery (in several cases with prior intraaortic balloon pumping) when no relief was obtained after 8 to 12 hours of maximal therapy with beta adrenergic blocking agents.[8]

Methods

Study 1

The methodology employed for the animal data quoted under Results has been published elsewhere and will not be repeated here.

For the first part of the clinical study, data were collected from 6 patients who underwent cardiac catheterization because of myocardial ischemia suspected to be secondary to spasm and from 10 other patients who have had bypass surgery 1 year before catheterization. In the latter group, a total of 26 pairs of radiopaque platinum markers had been implanted on the epicardium at operation. Seventeen of these marker pairs (in 10 patients) were placed on areas newly supplied by blood from the coronary arterial bypass graft, and nine pairs of markers (in 9 patients) were placed in areas not supplied by the coronary arterial system.

Patients with coronary spasm: Of the six patients with suspected coronary arterial spasm, two showed the full-fledged clinical syndrome of Prinzmetal's angina. During catheterization, spontaneous spasm was observed in three of the six, and in another two spasm was induced by intravenous injection of methergine (an ergot alkaloid similar to ergonovine). In the sixth patient, spasm was induced during manipulation of the catheter. In each patient, as soon as spasm was observed, the average dose of nifedipine (2 μg/kg body weight) was selectively injected into the coronary artery in spasm and biplane filming was performed (Fig. 1, Table I). This average dose had been selected as a result of previous studies in our laboratory.[9] No effort was made to test the patient's response to nitrates before administration of nifedipine.

Patients after coronary bypass surgery: During recatheterization of 10 postoperative patients a pacing catheter was placed into the right atrium (Fig. 2). Heart rate was fixed at 10 beats above the spontaneous rate present before the pharmacologic intervention. Left ventricular pressures were recorded with a double micromanometer (Millar PC770 or 780). The methodology for measuring regional shortening from epicardial radiopaque markers has been described in detail elsewhere.[10] In brief, the radiopaque marker pairs implanted in the epicardium at operation are filmed during synchronized biplane cinefluoroscopy at 50 frames/s. The absolute distances between each marker pair are calculated, with five consecutive heart beats being analyzed as a control set before intrabypass injection of nifedipine and again 30, 60, 120 and 180 seconds after the injection. During this period, variables derived from left ventricular pressure measurements are monitored continuously by means of the beat to beat analysis program of our cardiac catheterization laboratory computer.[11] Pressures were recorded for a period of 5 minutes before and during the injection of nifedipine. End-diastolic pressure, peak systolic pressure, peak positive first derivative of left ventricular pressure (dP/dt), cycle length, peak velocity of contractile elements (V_{ce}) and maximal velocity of contractile elements (V_{max}) were derived by means of the on-line computer program. In addition, an analysis of the isovolumic relaxation phase was carried out by calculating the peak negative dP/dt. The relaxation time constant was determined by a least-squares fit of a monoexponential equation describing the fall of left ventricular pressure from the moment

TABLE I

Arteriographic Findings and Effect of Nifedipine in Six Patients With Either Spontaneous or Induced Coronary Arterial Spasm

Case	Spasm	Arteriographic Findings (vessel and % obstruction)	Intracoronary Nifedipine*	Intravenous Nitroglycerin*
1	Methergine-induced	RCA (100%)	+	...
2	Methergine-induced	LCx (100%)	−	+
3	Spontaneous	RCA (75%)	+	...
4	Spontaneous	LAD (75%)	+	...
5	Catheter-induced	RCA (75%)	+	...
6	Spontaneous	LCx (100%)	+	...

* Immediate administration of intracoronary nifedipine relieved the obstruction completely in five of six patients; intravenous nitroglycerin proved effective in one.

LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; RCA = right coronary artery; + = effective; − = not effective; ... = not administered.

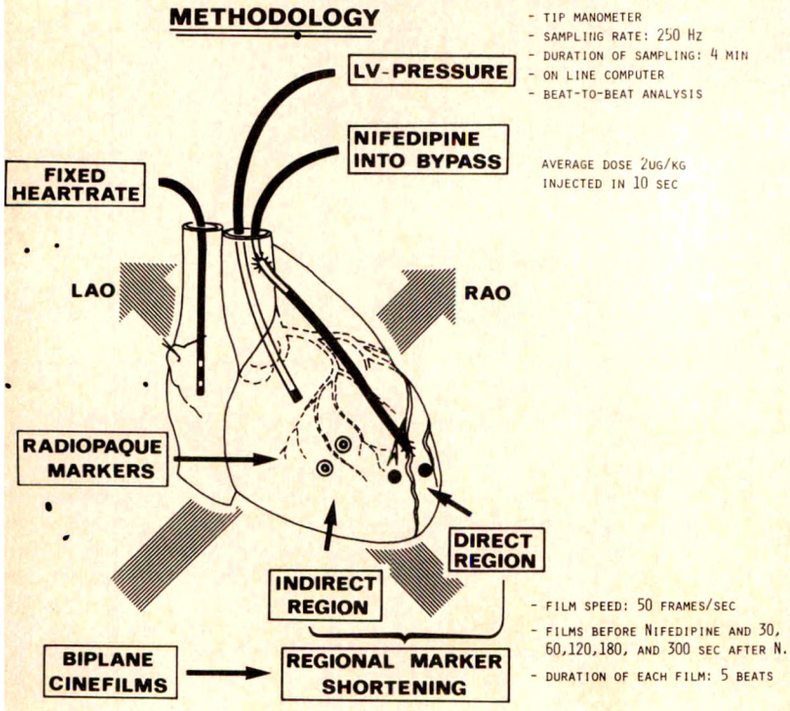

FIGURE 2. Diagram of the principal methods employed in the study. See text and Reference 10 for details on the measurement of regional shortening with radiopaque markers attached to the epicardium during coronary bypass surgery. LAO = left anterior oblique; LV = left ventricular; N. = nifedipine; RAO = right anterior oblique.

of peak negative dP/dt to that existing at a pressure of 35 mm Hg (Fig. 3).

Study 2

Patients with unstable angina: The second part of the study, was carried out between June 1, 1979 and January 1, 1980, when 720 patients with various symptoms of coronary artery disease were admitted to our coronary care unit. Forty-seven of these patients had precordial pain at rest that was typical of angina pectoris and that persisted or worsened. In all 47 patients, transient ST-T changes but no new Q wave formation were documented in the coronary care unit during angina at rest. The patients' serum enzyme levels were often elevated but in no instance reached values twice the normal in our laboratory.

On admission, all patients were placed in a private room, although they remained directly accessible to the nursing staff. Hemodynamic monitoring was initiated immediately by means of a Swan-Ganz thermodilution catheter advanced from the subclavian or right jugular vein or an arm vein into the pulmonary artery. If either hypotension or hypertension was present initially, a catheter was inserted into the left radial artery with use of local anesthesia. All patients received heparin intravenously (30,000 units or less every 24 hours). A semiautomated monitoring system facilitated continuous recording of heart rate, cardiac rhythm and pul-

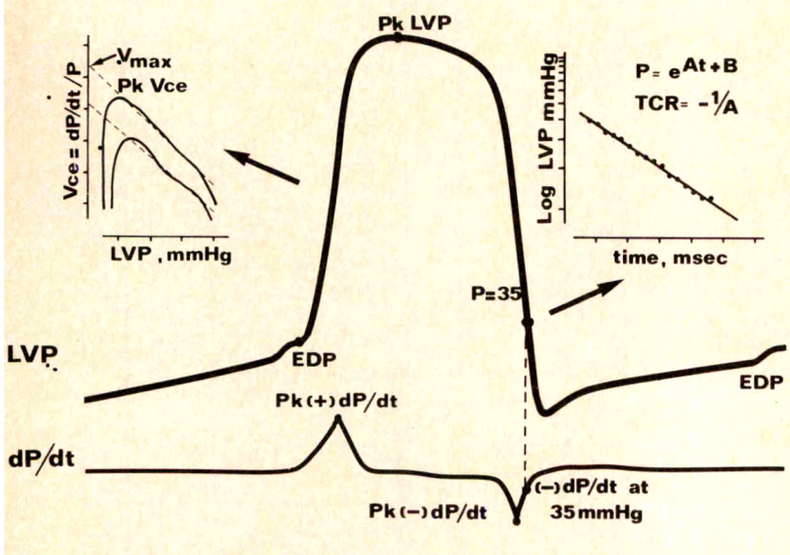

FIGURE 3. Isovolumic variables, as determined by the beat to beat analysis program of the catheterization laboratory computer system. dP/dt = rate of rise of left ventricular pressure; EDP = end-diastolic pressure; LVP = left ventricular pressure; P = 35 = pressure at 35 mm Hg; $P = e^{AT + B}$ = the constant and intercept of the regression line; Pk = peak; TCR = time constant for relaxation determined by slope (A) of pressure on log-linear plot; V_{ce} = velocity of contractile elements; V_{max} = maximal velocity of contractile elements.

monary arterial pressure, while systemic blood pressure and cardiac output were determined at regular intervals. During and after every attack of pain, a 12 lead electrocardiogram was recorded, and if pain persisted, the recording was repeated at 15 minute intervals. On admission and 6 hours after each attack of pain, creatine kinase, MB-creatine kinase and α-HBDH cardiac enzymes were measured.

After initial sedation, usually with oral diazepam (5 to 10 mg three times daily), the patient was given isosorbide dinitrate, 5 mg every 2 hours sublingually or, if necessary, intravenously. In addition, propranolol was administered intravenously at doses ranging from 1 to 10 mg until a heart rate of 60 beats/min was reached. Thereafter, propranolol was given orally at doses ranging from 400 to 800 mg every 24 hours. When propranolol was contraindicated, as in patients with lung disease, a cardioselective beta adrenergic blocking agent was chosen.

The 47 patients studied included 38 men and 9 women aged 29 to 77 years (mean 58). Three subgroups of patients could be identified: Twelve (group I) had no history of previous coronary artery disease, 25 (group II) had a history of long-standing coronary artery disease and the remaining 10 (group III) had a return of angina at rest within 2 weeks after discharge from the hospital where they had been treated for an acute myocardial infarction. Two patients in group II and one in group III had previously had coronary bypass grafting.

Results

Nifedipine injection into coronary bypass graft: Data collected from the patients studied during cardiac catheterization are shown in Tables I and II and Figures 4 and 5.[12] After direct injection of nifedipine into the coronary graft bypass the expected reduction in peak left ventricular systolic pressure occurred. There was also an increase in end-diastolic pressure as well as a marked decrease in peak positive dP/dt, peak negative dP/dt and V_{max}, and an increase in the relaxation time constant. All of these differences were statistically significant when compared with control measurements.

TABLE II

Pressure-Derived Variables After Intracoronary Bypass Injection of Nifedipine (10 injections, mean ± standard error of the mean)

	Control Value	Peak Effect
Peak LVP (mm Hg)	141 ± 8	124 ± 7*
EDP (mm Hg)	16 ± 2	26 ± 3*
Peak positive dP/dt (mm Hg/s)	1855 ± 118	1521 ± 73†
V_{max}(lengths/s)	55 ± 3	43 ± 2*
Peak negative dP/dt (mm Hg/s)	2133 ± 135	1575 ± 86*
Negative dP/dt at 35 mm Hg (mm Hg/s)	873 ± 43	598 ± 53†
Relaxation time constant (lengths/s)	39 ± 2	54 ± 3*

* $p < 10^{-5}$. † $p < 10^{-4}$.
dP/dt = rate of change of left ventricular pressure; EDP = end-diastolic pressure; LVP = left ventricular pressure; V_{max} = maximal velocity of contractile elements.

The shortening fraction during ejection, that is, the systolic phase of the cardiac cycle, was markedly decreased in the area directly perfused by the artery into which nifedipine had been injected (Fig. 4 and 5); in contrast, no changes were observed elsewhere in the heart. The onset of regional shortening was delayed and the shortening rate was diminished. Minimal length was shifted from end-systole to early diastole, as if contraction had continued during diastole.

These responses were previously observed in experimental animals in which regional wall thickness and blood flow in the left anterior descending coronary artery were measured in areas perfused by this artery after nifedipine was injected directly into it (Fig. 6A).[9] The difference between coronary arterial and pulmonary arterial infusion is shown in Figure 6. All changes in left ventricular variables were transient, and function returned to control levels within 5 minutes. All measurements were made at a constant rate of pacing, and direct slowing of contraction and relaxation must be inferred.

Oral nifedipine in unstable angina (Fig. 7): Sixteen of the 47 patients with unstable angina who were treated with propranolol or other beta blocking agents

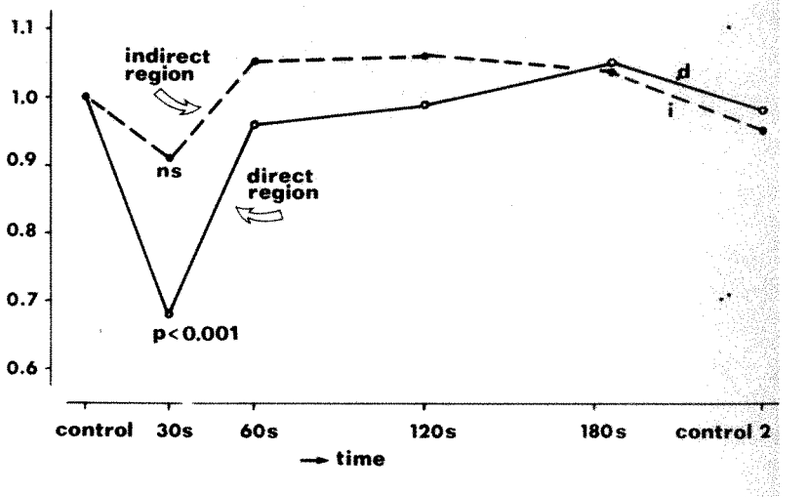

FIGURE 4. Normalized shortening fraction during ejection in selective regions as determined by movement of radiopaque markers (direct [d], n = 17) and independently perfused marker pair regions (indirect [i], n = 9). Values shown are relative changes from control values. Within 30 seconds of injection of nifedipine into the bypass graft a large and significant decline in the regional ejection fraction of the myocardium perfused by the bypass graft occurred (direct region) and recovery occurred rapidly; this was accompanied by only a small reduction in the localized ejection fraction of the myocardium not perfused by the graft.

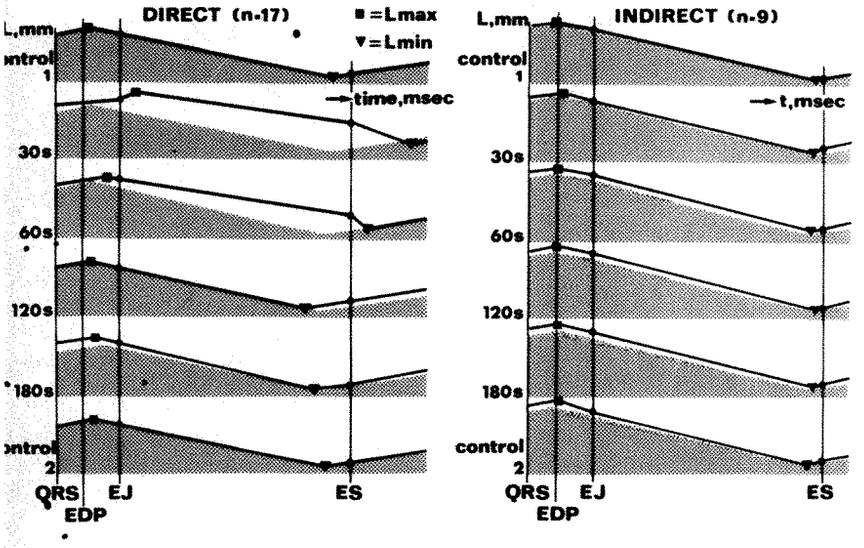

FIGURE 5. Regional shortening measured with pairs of radiopaque markers in (**left**) region of myocardium into which nifedipine had been injected (direct, n = 17) and (**right**) other regions of myocardium (indirect, n = 9). **From top to bottom:** Control period and 30, 60, 120, and 180 seconds after intrabypass injection of nifedipine. The **shaded area** represents the shortening pattern of the first control period. In selectively injected regions, the onset of regional shortening (L_{max}) is delayed, the shortening rate is diminished, and L_{min} is shifted from end-systole to early diastole. EDP = end-diastolic pressure; EJ = ejection; ES = end-systole. Left panel reproduced from Serruys et al.[12] by permission of the American Heart Association, Inc.

nd nitrates became asymptomatic 3 to 8 hours after the nset of treatment. Of the other 31 patients who, in ddition, received oral nifedipine in doses of 10 mg six mes a day, 27 became asymptomatic within 1.5 hours nd remained so for the remainder of their hospital stay; patients did not respond to nifedipine. Two of these ıstained a myocardial infarction within 24 hours, and ne died. Because of persistent pain, two other patients nderwent intraaortic balloon pumping, with immeiate relief of symptoms.[8] Both underwent coronary ypass grafting and both are alive. Coronary arteriogıphy showed that three of these four patients had more han 75 percent obstruction in three vessels, while the ɔurth patient, a 73 year old man, had 90 percent obtruction of the left main coronary artery and had a fatal ıyocardial infarction shortly after coronary arteriogıphy.

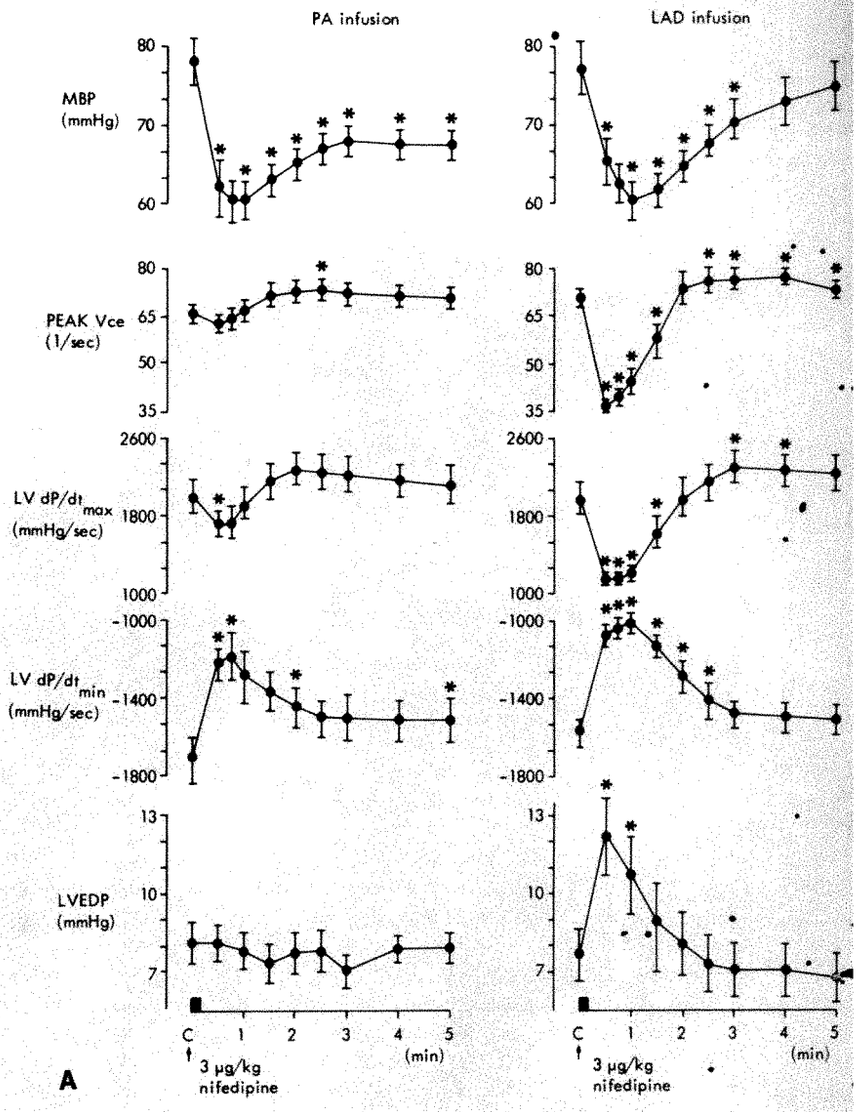
Twenty of the 27 patients who experienced initial elief of symptoms when nifedipine was added to the herapeutic regimen underwent elective coronary arıriography and left heart catheterization after they esumed some degree of physical activity in the interıediate care unit. However, one patient with postinırction angina (group III) sustained a fatal myocardial ıfarction before catheterization and within 7 days of ıitiation of nifedipine treatment. Of the 19 patients ndergoing catheterization, 1 had greater than 90 perent cross-sectional obstruction of the left main coroary artery and 9 had three vessel, 3 had two vessel and ix had one vessel coronary artery disease with greater han 75 percent obstruction.

Follow-up: In addition to the patient with fatal inırction, four other patients had a nonfatal infarction ıithin 2 weeks after the initial relief of symptoms. In wo of these patients, the event was related to angiogıphy; both had extensive pain, with ST-T changes and slight rise in cardiac enzyme levels but without new) wave formation. In one of the other two patients oronary arterial spasm was documented during angiography and injection of nifedipine into the involved coronary artery led to immediate relief.

Thus, of the total group of 27 patients who were managed with nifedipine and who became asymptomatic, 5 sustained an infarction (fatal in 1) within 2 weeks after initial stabilization. During further follow-up (3 to 5 months) no other instances of myocardial infarction were noted. Thus far, 15 of the 19 patients who underwent catheterization have undergone elective coronary bypass grafting. In these patients, the indication for operation consisted of a past history of unstable angina and an advanced degree of coronary arterial stenosis. All are alive and well. The other 11 patients have remained asymptomatic and have been maintained on nifedipine therapy.

Discussion

Effect of nifedipine on coronary spasm and on myocardial contraction (local contractile arrest in presence of increased coronary flow): The two parts of this study were carried out in patients with proved or suspected coronary arterial spasm. From the data in Table I, there is little doubt that in the majority of patients, direct intracoronary injection of nifedipine yields prompt relief when spasm can be demonstrated. Other authors,[2–6] using a variety of techniques, have demonstrated that this calcium blocking agent has a similar beneficial action. In addition, the data shown in Figures 4, 5, and 8 indicate that locally administered nifedipine acts directly on the myocardium. Measurements of the changing distances between radiopaque markers placed on the epicardium (Fig. 5) indicate that major changes in wall motion take place as early as 30 seconds after injection of nifedipine. The distance between the markers is substantially increased, with a reduction in regional shortening to approximately 67 percent of the control value. The rate of systolic shortening is significantly diminished, indicating a slowing of the local contractile process; the separation between the marker



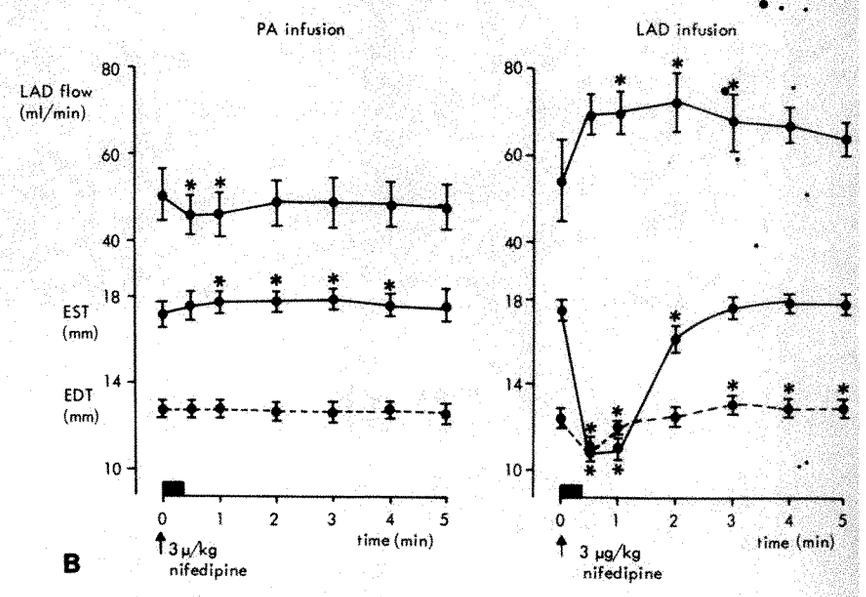


FIGURE 6. A, Hemodynamic changes after administration of 3 μg/kg of nifedipine into the pulmonary artery (PA) and into the left anterior descending coronary artery (LAD) of the same pig. Note that the effects on mean arterial blood pressure (MBP) and the rate of fall of left ventricular pressure (LV dP/dt_{min}) are independent of the site of injection, whereas the magnitude of the effects on myocardial contractility (peak V_{ce} and LV dP/dt_{max}) and ventricular filling pressure (LVEDP) are dependent on the site of the injection. The heart was paced at 104 beats/min.* $P < 0.05$ compared with baseline. **B,** left anterior descending coronary arterial (LAD) blood flow (from an electromagnetic flowmeter) and myocardial wall thickness after administration of 3 μg/kg of nifedipine into the pulmonary artery (PA) and the left anterior descending coronary artery. Injection into the pulmonary artery had no effect, that into the left anterior decending artery caused a transient decrease, mainly in end-systolic thickness (EST). After 3 minutes, a rebound in end-diastolic thickness (EDT) was observed (0.5 mm larger than baseline value). *$p < 0.05$ compared with baseline value.

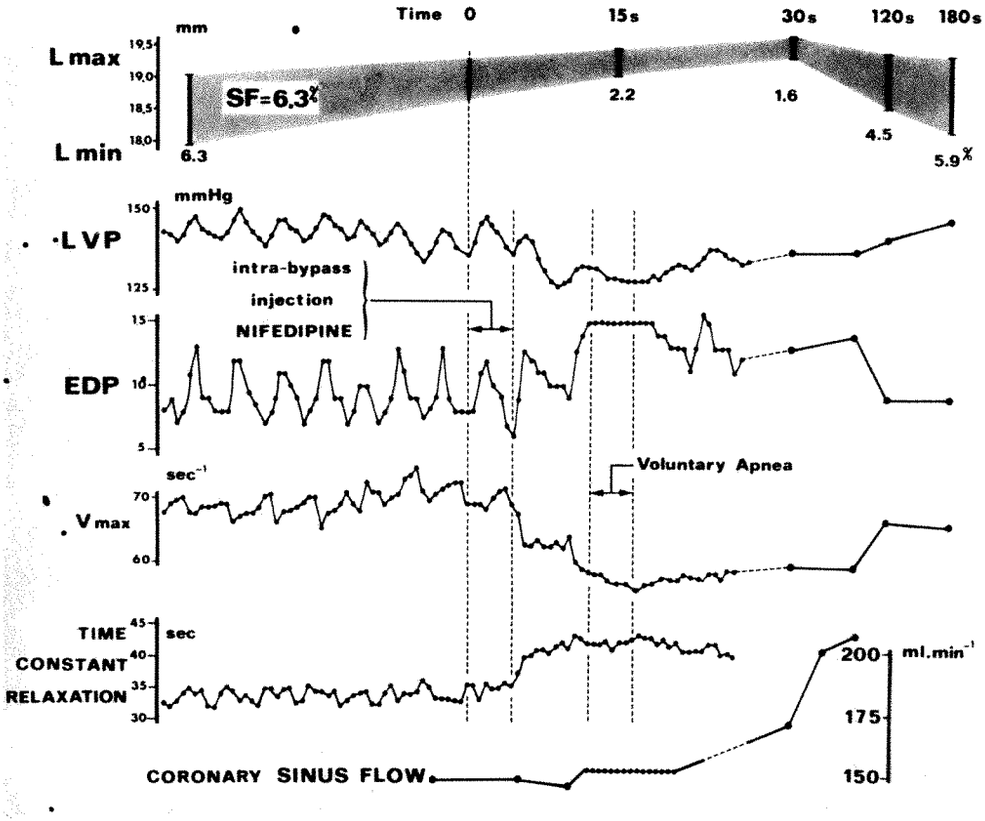

FIGURE 7. Continuous plot of marker distance (L_{max}, L_{min}) with shortening fraction, left ventricular pressures (LVP and EDP), V_{max} and the relaxation time constant of the region perfused by an injection of nifedipine into a patent bypass graft. In this patient, coronary sinus flow was measured continuously. Shortly after intrabypass injection of nifedipine, the shortening fraction (SF) decreased from 6.3 to 2.2 percent, accompanied by a rapid rise in end-diastolic pressure and decreases in V_{max} and left ventricular peak pressure. Simultaneously coronary sinus flow increased from 150 to more than 200 ml/min.

pairs reaches a minimum 80 ms after closure of the aortic valve, indicating that contraction became prolonged; in fact, at the peak of action of nifedipine, 38 percent of total regional shortening took place during early diastole of the ventricle as a whole. None of these changes were seen when marker distances were measured in the same patient in areas not perfused by nifedipine.

These observations complement published results from studies performed in our laboratory in the open chest pig[9] when nifedipine, in a dose of 3 μg/kg, was administered over 20 seconds into the left anterior descending coronary artery (Fig. 6). In these animals, coronary arterial flow, measured simultaneously from an electromagnetic flowmeter, showed a marked increase during the first 3 minutes after injection, and systolic thickening of the ventricular wall decreased from 18 to 11 mm during the same time. In other words, end-diastolic thickness decreased, systolic thickening was virtually abolished, and the process of contraction became extended into what is early diastole for the remainder of the ventricle. Yet, at the same time, flow in the left anterior descending coronary artery increased by 40 percent above its control value. None of these changes occurred in animals when the same dose of drug was infused into the pulmonary artery.

Similar findings have been documented in several patients. Data from one of these patients (Fig. 7), measured beat by beat over a period of 300 seconds, clearly show the immediate effect of nifedipine on ventricular wall dimensions, end-diastolic pressure, and V_{max}. Perhaps most important, in terms of the mechanism of action of the drug, the relaxation time constant increased by some 50 percent. All of these values could also be reliably measured during a period of voluntary apnea, showing that respiratory influences were minimal. The effects of nifedipine were maximal 30 seconds after injection, at which time the shortening fraction was barely 1.6 percent and V_{max} was at its lowest, yet coronary sinus blood flow had increased 200 ml/min. These appear to be extremely favorable responses for the ischemic myocardium.

These human and animal experiments complement each other and indicate that there is marked local contractile "arrest" in the presence of increased coronary flow. These data also complement those originally presented by Grün and Fleckenstein[13] and Vater,[14] who demonstrated that similar doses of nifedipine led to significant reductions in myocardial oxygen consumption in regions perfused by the coronary artery into which the drug had been injected.

Beneficial effects of nifedipine therapy for unstable angina: This series of observations, indicating an "oxygen-sparing" effect of nifedipine, led to our use of the drug in patients with unstable angina (Fig. 8 and 9). Indeed, the hypothesis has been put forward that the subset of patients with suspected coronary arterial spasm may receive no benefit from beta adrenergic blocking agents, and Yasue et al.[4] have specifically argued against their use in this group of patients. Rather, when beta adrenergic blockade has failed to relieve symptoms—despite its reduction of heart rate and

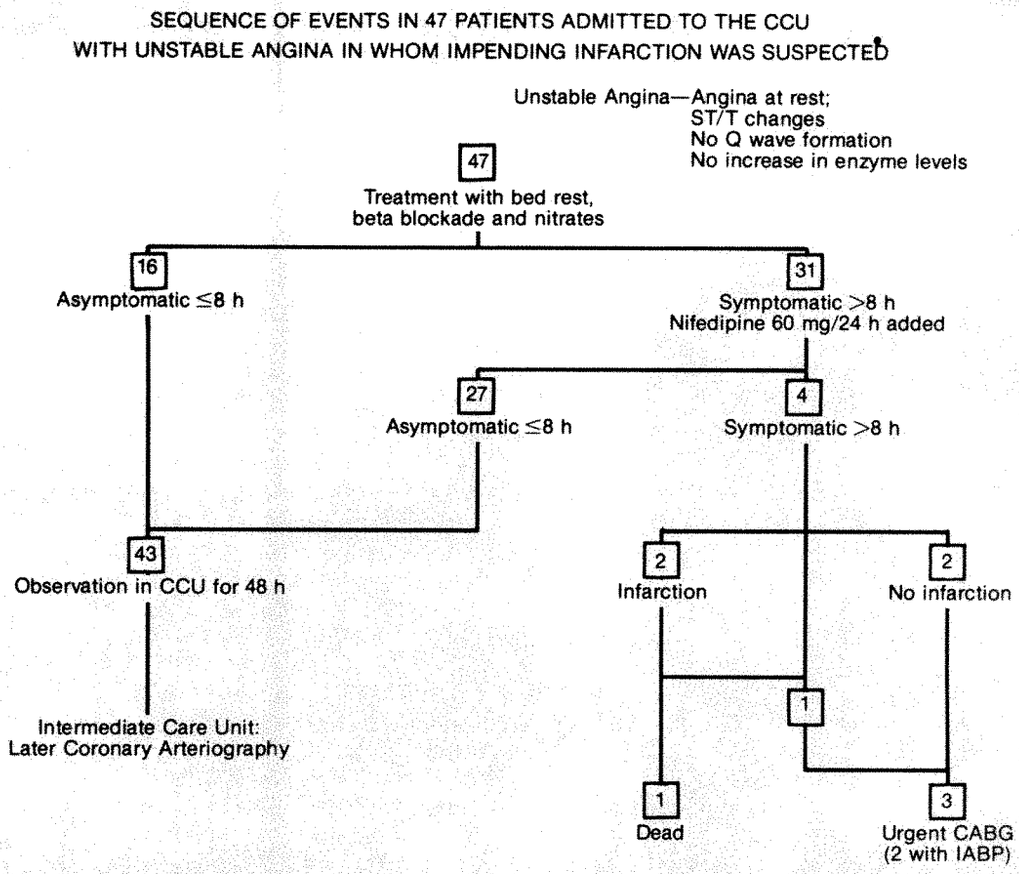

FIGURE 8. Schematic view of developments in 47 patients with suspected impending myocardial infarction. CABG = coronary arterial bypass grafting; CCU = coronary care unit; IABP = intraaortic balloon pumping.

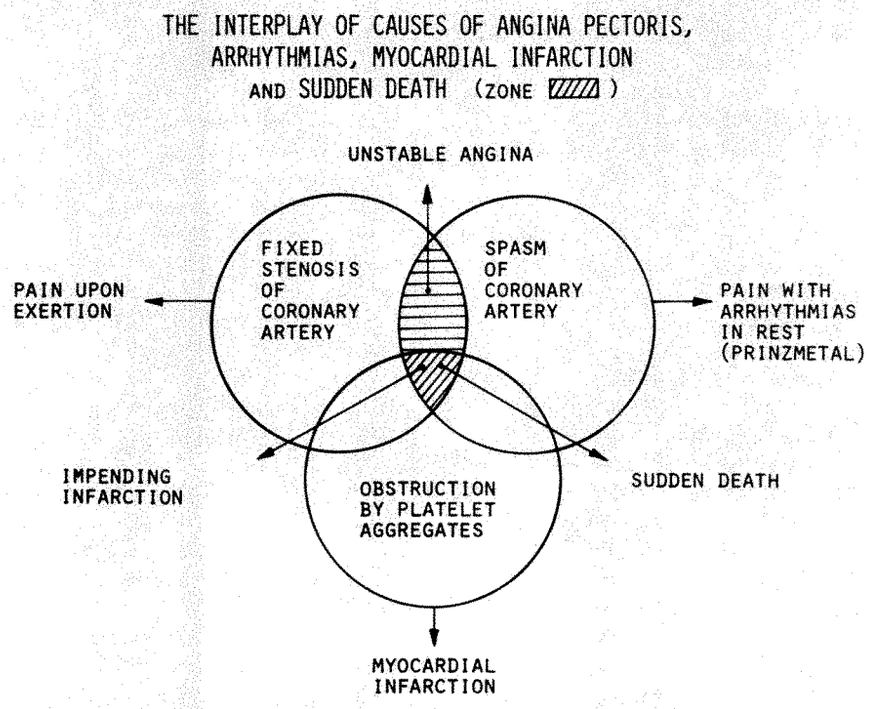

FIGURE 9. Schematic view of the interplay of the three main causes of unstable angina: fixed stenosis of coronary arteries, coronary arterial spasm, and coronary arterial obstruction by platelet aggregates. Nifedipine appears to have its most useful application in the **horizontally hatched area.**

ompetitive blocking at beta receptor sites—the addi-ion of nifedipine, or perhaps the use of nifedipine alone, nay be the more logical approach. Theoretically, the nhibition of transmembrane calcium influx into cardiac nuscle fibers results in less phosphate-bound energy eing transformed into mechanical work by calcium-lependent myofibrillar adenosine triphosphate (ATP), vhich in turn leads to a reduction in cardiac oxidative netabolism; oxygen need is therefore diminished. In ddition, the reduction in the calcium-dependent con-ractile tone of the larger epicardial coronary arte-ies—and perhaps to some extent the capillaries as vell—indicated by the sudden reduction of ventricular vall thickness (Fig. 6B) leads to increased flow and thus apidly restores the regional oxygen concentration to ıormal. In addition to these changes, dilation of large eripheral arteries will diminish afterload and may re-ult in a further, indirect reduction in cardiac oxygen lemand.

Henry et al.[15] have indicated that even when an area ıround an infarct is rendered ischemic, a reduction in he quantity of ischemic cells can be achieved with ni-edipine. In those patients in our group who did not espond to beta adrenergic blockade, nifedipine pro-luced similar dramatic and sudden results. Although his study was not randomized and in many other re-pects did not meet the requirements of a strict clinical rial, the reduction in symptoms was impressive. Twenty-seven of the 31 patients treated with nifedipine n addition to beta blocking agents became asymp-omatic within a very short period of time and remained o in nearly all instances. Given the brittle clinical state f these patients, and the failure of all other supportive herapy, it is highly likely that nifedipine was respon-ible for the improvement. In fact, in the four patients n whom nifedipine did not evoke a similarly favorable esponse, the extent of fixed organic stenosis, as dem-nstrated on coronary arteriography, was severe enough hat the lack of response to a spasmolytic agent was ıardly surprising. The subsequent response of these atients to intraaortic balloon pumping and emergency ypass surgery underscores that their obstructive le-ions were mainly of an organic nature. Under these onditions, the action of nifedipine may well be less pecific and unique.

Role of coronary spasm in unstable angina in resence of severe atherosclerotic disease: In this egard it is of interest to examine the coronary arterio-raphic findings in 20 of the 27 patients who responded romptly to nifedipine and to discuss briefly the rate f myocardial infarction. One patient with postinfarc-ion angina died 7 days after admission to the coronary are unit, just before the planned catheterization. Au-opsy showed extensive three vessel disease, including arrowing of the left main coronary artery. As indicated arlier, of the remaining 19 patients, 1 had greater than 0 percent narrowing of the left mainstem, and 9 had hree vessel disease, 3 had two vessel disease and 6 had ne vessel disease with more than 90 percent obstruc-ion. To date, 15 of these 19 patients have undergone bypass grafting and 4 sustained a nonfatal myocardial infarction before they could be operated on—in immediate relation to the cardiac catheterization procedure in 2 and after discharge from the hospital in 2. The 15 patients operated on are asymptomatic and no longer receive nifedipine therapy; the 11 patients not operated on are also asymptomatic but still receive nifedipine therapy.

These findings indicate the presence of severe atherosclerotic coronary artery disease in 14 of the 20 patients studied. It is suggested that the symptoms in the remaining 6 patients approximate those of Prinzmetal's syndrome although the complete manifestations thereof could not be observed during the acute phase. Because of the prompt response to nifedipine, spasm would seem to have been the dominant mechanism. In those patients with a long-standing history of coronary artery disease and severe atherosclerotic disease spasm probably played only a secondary role, although it was equally responsive to nifedipine.

Therapeutic failures and occurrence of myocardial infarction: In the four patients who did not respond to nifedipine therapy the rapidity of the subsequent events suggests that treatment with nifedipine had commenced too late. Five of the 27 patients who responded to nifedipine nevertheless sustained an infarction in the subsequent weeks compared with 2 of the 4 nonresponders. Because 1 of the 5 responders had had a previous infarction (group III) and in 2 (both from group II) the infarction occurred during coronary arteriography, nifedipine therapy can be considered to have failed in only 2 (7.4 percent) of the 27 patients in the longer term. This incidence relates favorably to the generally quoted incidence of myocardial infarction, which ranges from the 13 percent in the Rotterdam IMIR study[17] to 23 percent reported by Vakil,[18] in these severely ill patients with impending infarction. Incidentally, in our study the two responders to nifedipine with subsequent infarction had three vessel disease during coronary arteriography.

Therapeutic implications: We believe that nifedipine should be added to beta adrenergic blocking drugs when the latter show no immediate effectiveness in patients presenting with angina at rest. The combination of nifedipine and a beta blocking agent has not been shown to cause any adverse hemodynamic effects. In our opinion, nifedipine deserves further clinical evaluation for use in unstable angina.

Nifedipine inhibits myocardial contractility while increasing coronary blood flow and this combination of actions may help prevent myocardial infarction in patients who have unstable angina with a substantial vasospastic component (Fig. 9). However, those patients with advanced fixed organic obstructions do not respond as well.

Acknowledgment

The supplies of nifedipine (Adalat®) used in our study were graciously made available by the Bayer Company, West Germany.

Treatment of Prinzmetal's Variant Angina

Role of Medical Treatment With Nifedipine and Surgical Coronary Revascularization Combined With Plexectomy

MICHEL E. BERTRAND, MD, FACC
JEAN-M. LABLANCHE, MD
PIERRE Y. TILMANT, MD

Lille, France

This study describes three forms of treatment of Prinzmetal's variant angina. Coronary spasm, frequently found at coronary arteriography in patients with Prinzmetal's variant angina, can be treated with intravenous or intracoronary injection of nitroglycerin as well as of nifedipine. Nifedipine (0.2 mg) was injected directly into the involved artery in 12 patients and suppressed spasm in 9; in 3 patients, nifedipine increased coronary sinus flow, which had been decreased by spasm in one of the branches of the left coronary artery.

Patients with Prinzmetal's variant angina who have spasm superimposed on atherosclerotic lesions can benefit from coronary arterial bypass grafting combined with partial denervation of the heart. This combination yielded acceptable results (83.4 percent favorable outcome); recurrence of attacks occurred in only 6.7 percent of this group. In those forms of angina in which spasm occurs in angiographically normal coronary arteries, therapy is essentially medical. In 13 patients treated with oral nifedipine (30 to 40 mg/day), suppression of attacks was achieved in 11 instances. During the period of treatment, the methergine provocative test, which had been consistently positive before treatment, converted to negative in 12 patients. Transient withdrawal of nifedipine caused recurrence of pain in two patients.

Over the past 5 years, it has been demonstrated that the treatment of Prinzmetal's angina differs from that of typical angina pectoris. Beta adrenergic blocking agents, effective in the treatment of typical angina, do not achieve similar results in Prinzmetal's angina[1–4] and may even intensify anginal attacks.[5,6] Surgical treatment, when feasible, provides poorer results in Prinzmetal's angina than in the other forms of angina pectoris; that is, the rates of mortality and perioperative infarction are higher,[7,8] the number of occluded grafts is larger, and the recurrence of attacks is common.

One reason for these differences may be the presence of coronary arterial spasm. The incidence of spasm in Prinzmetal's angina has been variously estimated to be between 20 and 87 percent.[9,10] Among 70 patients with variant angina, we have observed spasm to occur spontaneously in 46 instances, an incidence rate of 66 percent. However, since the advent of provocative testing,[11] the incidence of spasm has been found to be considerably greater; among 45 patients recently examined, for example, we observed spasm in 42, an incidence rate of 93.5 percent. Thus, spasm appears to be an important and frequent phenomenon in Prinzmetal's angina.

Various drugs have been used to abolish the spasm observed during coronary arteriography. We have proved the usefulness of nifedipine

when it is injected directly into the coronary vessel affected, and the first part of this paper will describe this observation.

Long-term treatment of patients with Prinzmetal's angina depends on whether the spasm is superimposed on fixed organic atherosclerotic lesions or whether it occurs in angiographically normal arteries. Among 70 of our patients with Prinzmetal's angina, 20 (29 percent) had angiographically normal coronary arteries; the remaining 50 (71 percent) had fixed atherosclerotic lesions. The arteriographic status of the coronary arteries should be kept in mind when long-term treatment is considered.

Methods

Selection of patients: All patients in this study fulfilled the following criteria for variant angina pectoris: recurrent angina at rest associated with S-T segment elevation (greater than 2 mm) in leads other than those reflecting an area of an old infarction, with return of the S-T segment to control levels after relief of pain and without evolution of myocardial infarction as manifested in serial electrocardiograms or cardiac enzyme determinations. All patients underwent coronary arteriography. The procedure included left ventricular cineangiography performed in the 30° right anterior oblique projection, and selective coronary arteriography was performed in six projections for the left coronary artery and five projections for the right coronary artery.

When spontaneously occurring coronary arterial spasm was not observed, a provocative test was performed according to a technique previously described.[12] The test consisted of a single intravenous injection of 0.4 mg of methergine, an ergot alkaloid similar to ergonovine maleate. The methergine challenge was repeated in several patients either at the time of arteriographic examination of the grafts or in an intensive care unit in accordance with the technique described by Nelson et al.[13]

The present study included 55 patients with variant angina who were separated into three groups:

Group A: Treatment of coronary spasm with direct injection of nifedipine into the affected coronary artery: This group included 12 patients with Prinzmetal's variant angina. Three of these patients experienced spontaneous spasm during coronary arteriography and in nine others spasm was induced by the provocative test. Spasm occurred in the left anterior descending artery in four patients, in the right coronary artery in three and in the left circumflex artery in four; in one patient it involved two arteries (left anterior descending and circumflex coronary arteries). After documentation of the spasm, nifedipine (0.2 mg) was injected directly into the affected vessel. If the spasm persisted for more than 2 minutes, nitroglycerin was injected intravenously. In three patients, coronary sinus blood flow was measured according to the technique described by Ganz et al.[14] before and during methergine-induced spasm and after intracoronary injection of nifedipine.

Group B: Treatment of Prinzmetal's angina by plexectomy associated with aortocoronary bypass grafting: This group included 30 patients with variant angina who ranged in age from 40 to 70 years. On coronary angiography 15 of these patients had significant obstruction of one vessel, 6 of two vessels and 9 of three vessels. All 15 patients had lesions considered suitable for coronary bypass grafting. Coronary arterial spasm was observed in 19 patients; spasm was spontaneous in 6 patients and was provoked by methergine in 13 others. The surgical procedure combined coronary bypass grafting with denervation of the heart to prevent recurrence of spasm. The denervation (plexectomy) was carried out before the bypass grafting and included four steps:

1. To avoid spasm induced by manipulating Wrisberg's ganglion (sympathetic fibers in the subaortic and retroaortic areas), a large bolus dose of lidocaine was infiltrated just beneath the root of the aorta.
2. The adventitia overlying the aorta was peeled from the left vagus laterally, to the most anterior aspect of the ascending aorta, medially.
3. Meticulous resection of all the ganglia and nerves located under the aortic root in Wrisberg's space was performed; this included resection of the entire triangular shaped tissue located between the trachea and the ascending aorta.
4. Dissection of the space between the descending aorta and the main pulmonary trunk and resection of the nerves to the right coronary artery.

Thus, resection of as much as possible of the major cardiac plexus located anteriorly near the base of the aorta and under the aortic root was performed. Cardiopulmonary bypass was started and conventional aortocoronary bypass grafting was carried out. Fifteen patients received a single coronary graft, six received two grafts and nine received three grafts. Patients were followed up in accordance with the following criteria: (1) clinical response; (2) resting electrocardiogram and 24-hour ambulatory electrocardiographic monitoring; and (3) provocative test with methergine.

Group C: Treatment of Prinzmetal's angina in patients with angiographically normal coronary arteries: This group included 13 men with variant angina who ranged in age from 21 to 74 years. Coronary arteriography revealed totally normal coronary arteries in eight patients and minimal irregularities with no significant stenoses in five. Provocative tests with methergine were performed in all 13 patients. Coronary arterial spasm in seven patients was localized to the right coronary artery, in two patients to the left anterior descending artery and in three to the left circumflex coronary artery. In one patient spasm involved both the left anterior descending artery and the circumflex artery. Ten patients were treated with 30 mg of nifedipine/day and three received 40 mg/day. Treatment was continued for an average period of 15 months (3 to 29) with six patients receiving nifedipine therapy for more than 1 year. Patients were followed up in accordance to the criteria for patients in group B.

Results

Treatment of coronary spasm with direct injection of nifedipine into the affected coronary artery (Table I): In eight patients, spasm disappeared completely within 2 minutes of the intracoronary injection of nifedipine. In one patient, spasm involved two vessels (left anterior descending and left circumflex arteries) and was attenuated but not entirely suppressed, and it was necessary to inject nitroglycerin to achieve complete relief. In three patients, injection of nifedipine had no effect, and when the spasm persisted beyond 2 minutes, nitroglycerin was injected intravenously. This maneuver abolished the spasm rapidly and completely. The vasodilator action of nifedipine injected into the affected artery seems to be of short duration. In one patient, methergine-induced spasm of the right coronary artery disappeared after injection of nifedipine into the affected vessel. Ten minutes later, spasm was induced in the same vessel with 0.4 mg of methergine; however,

TABLE I

Results of Injection of Nifedipine Into the Coronary Artery in 12 Patients With Spasm

Case	Spasm	Location of Spasm	Nifedipine Effect	Nitroglycerin Effect
1	Provoked	LAD 100%	+	
2	Provoked	LAD 100%	−	+

9	Provoked	LAD 75%, LCx 75%	+/−	+
10	Spontaneous	RCA 75%	+	
11	Spontaneous	LAD 75%	+	
12	Spontaneous	LCx 100%	+	

LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; RCA = right coronary artery; + = spasm relieved; − = spasm not relieved.

subsequent injection of nifedipine into the left coronary artery did not relieve the spasm. These results suggest that the drug has a direct effect, but this hypothesis remains to be confirmed by further studies.

In the three patients whose coronary sinus blood flow was measured before and during methergine-induced spasm, the latter was observed to occur in the left anterior descending artery (two patients) and in the left circumflex artery (one patient). During spasm, the flow decreased; after injection of nifedipine, the flow increased and exceeded baseline levels.

Treatment of Prinzmetal's angina by plexectomy associated with aortocoronary bypass: During the immediate postoperative period, 2 of the 30 patients died (surgical mortality 6.7 percent); 1 death was related to a low cardiac output, and 1 patient died with an intractable arrhythmia. One patient exhibited new Q waves in the electrocardiogram during the perioperative period. Of the 28 patients who survived operation, all were alive at the end of the follow-up period which averaged 23 months (range 3 to 48). At the end of the follow-up period all but two patients were asymptomatic and the latter had neither syncope nor heart failure. Two patients had recurrent attacks of angina. Recatheterization was carried out in 12 patients in order to evaluate the patency of grafts and in them all 14 grafts were patent. The methergine challenge was repeated in 21 patients. The challenge was performed at the time of arteriographic examination of the grafts in 12 patients or in the intensive care unit in accordance with the technique described by Nelson et al.[13] in 9 patients. In 20 patients the test did not provoke coronary arterial spasm or S-T segment change. In one patient who experienced recurrent attacks 3 months after the operation, coronary arteriography demonstrated that the graft, a bypass of the left anterior descending artery, was patent but spasm with S-T segment elevation could be induced by the provocative test. This patient was given nifedipine (40 mg orally/day) together with isosorbide dinitrate. He became asymptomatic, and further provocative testing was unable to induce electrocardiographic changes.

Treatment of Prinzmetal's angina in patients with angiographically normal coronary arteries: Treatment with nifedipine was continued for an average of 15 months (3 to 29) (Table II). Adverse effects were observed in two patients: One complained of cutaneous paresthesias and heat sensation but did not require discontinuation of therapy; the other experienced nausea and vomiting that necessitated withdrawal of the drug after 8 months of treatment.

Complete suppression of anginal attacks was achieved in 11 of 13 patients. Because of gastrointestinal intolerance, one patient had to discontinue therapy, whereupon the attacks recurred. Another patient had to interrupt treatment transiently and he also had a recurrence of attacks that disappeared completely when treatment with nifedipine was resumed.

Clinically, therefore, it may be concluded that highly satisfactory results were achieved during administration

of nifedipine in 11 of 13 patients. However, since it is well known that ischemic attacks, as documented by electrocardiographic monitoring, can occur in the absence of pain, the additional use of continuous Holter monitoring is justified. In all but one patient, a 24-hour electrocardiogram failed to show any evidence of ischemic attacks. The only patient whose attacks recurred in association with S-T segment elevation was one of the two patients whose anginal pain persisted. The provocative test was repeated in the 13 patients, with several being challenged two or three times during the follow-up period (32 tests). In 12 patients, electrocardiographic changes could not be induced by intravenous injection of 0.4 mg methergine. All of these patients had previously had a positive provocative test. Only one patient, who had had persistent pain and ischemic attacks during Holter monitoring, showed significant S-T segment elevation associated with pain.

Discussion

Intracoronary nifedipine versus nitroglycerin for acute coronary spasm: It is well known that arterial spasm observed at coronary arteriography can be suppressed with the administration of nitroglycerin, given either orally or, preferably, by intravenous injection. We have observed that when this drug was injected directly into the coronary artery affected by the spasm, it was abolished rapidly. In light of these results, we have studied the action of nifedipine injected directly into the vessel undergoing spasm. The initial results are promising. They show that when selectively injected into a coronary artery, nifedipine acts as a powerful vasodilator capable of suppressing spontaneous or methergine-induced spasm. However, from our limited experience, nifedipine seemed to show a slight delay in relieving spasm when compared with nitroglycerin. Moreover, since 3 out of 12 patients with coronary artery spasm did not respond to intracoronary nifedipine, it can be concluded that intracoronary nitroglycerin is the preferred treatment of these patients.

Surgical treatment of spasm in presence of fixed coronary stenosis: The long-term treatment of patients with Prinzmetal's angina depends on the arteriographic status of the coronary arteries. When coronary arteriography shows evidence of atherosclerotic lesions with or without superimposed spasm, two possibilities may be considered: (1) If the lesions are not operable (distal lesions, a narrow or stenosed vascular bed downstream, poor ventricular function), only medical treatment, that is, calcium antagonists and nitrates, should be employed. (2) If the lesions are amenable to coronary bypass surgery, the decision to operate is still subject to controversy.

The results of surgical treatment of Prinzmetal's angina are not as favorable as in angina pectoris on effort. Limet's review[15] of the published data showed that 33 percent of 214 patients had poor results; death and acute myocardial infarction each occurred in 11 percent. Rates of graft occlusion were much higher in these patients than those operated on for chronic stable angina pectoris. However, of greatest importance, anginal attacks persisted in a large number of patients. Clinically favorable results were obtained in only about 50 percent of patients. One possible reason for this difference between the results of patients with Prinzmetal's angina and those obtained in chronic stable angina may be the persistence of coronary spasm despite bypass surgery, causing obstruction of the vessel distal to the grafts. We have observed this phenomenon on two occasions. However, persistence of anginal pain may also be due to spasm occurring in another artery that may have appeared normal on preoperative arteriography.

It therefore appears reasonable that treatment of Prinzmetal's angina associated with fixed organic lesions should have a double aim: (1) to bypass the fixed lesions and (2) to suppress the spasm. Various authors[6–16] have suggested that Prinzmetal's variant angina is characterized by dysfunction of the autonomic nervous system. We recently observed that manipulation of Wrisberg's ganglion induced S-T segment elevation in two patients with Prinzmetal's angina. Thus, it appeared appropriate to consider combining coronary arterial bypass grafting with partial denervation of the heart in order to prevent the recurrence of spasm.[17] This surgical procedure, first described by Arnulf,[18] was employed in two patients with Prinzmetal's angina by Grondin and Limet.[8] Their two patients remained asymptomatic for more than 12 and 18 months, respectively. The results obtained in our series of 30 patients confirm their preliminary findings and suggest that plexectomy associated with aortocoronary bypass grafting could improve the results of surgical treatment in variant angina with organic narrowing. However, the plexectomy must be well performed. The rich network of fibers explains why plexectomy can be incomplete, especially as in relation to the posterior plexus, and an incomplete resection can explain the recurrent attacks observed in one of our patients. Nevertheless, these preliminary results should be interpreted with caution because of obvious difficulties in evaluating the effects of treatment of Prinzmetal's angina, which is characterized by considerable spontaneous variability of symptoms. Therefore, randomized trials of this procedure will be of considerable interest.

Oral nifedipine for prevention of spasm in normal coronary arteries: In the absence of stenotic lesions, treatment is confined to the prevention of coronary arterial spasm, which appears to be the key factor in triggering the attacks. Various drugs have been used in this subgroup of patients with angina—phenoxybenzamine,[19–21] atropine,[2–19] long-acting nitrates and verapamil[21] and amiodarone[22]—but treatment currently involves primarily the administration of calcium antagonists.

Spasm may be caused by various factors leading to contraction of the smooth muscle fiber, which depends on the calcium concentration in the medium. The usefulness of calcium antagonists in the treatment of Prinzmetal's angina has been reported in different studies.[20,23,24] Our results are similar to those obtained by Heupler and Proudfit[23] and Goldberg et al.[24] in coronary spasm refractory to other types of therapy. A European Cooperative study including 159 patients also

found that nifedipine prevented the recurrence of attacks in 75 to 83 percent of patients with Prinzmetal's variant angina. The results obtained with nifedipine in Europe are similar to those obtained by Hosoda and Kumura[25] and Endo et al.[2] More recently, Waters et al.[26] reported a rise in the threshold of response to an ergonovine challenge after administration of nifedipine.

Clinical implications: Although still undefined just a few years ago, a strategy for the treatment of Prinzmetal's angina is beginning to emerge. The basic therapy for spasm that occurs during coronary arteriography is the intravenous or, preferably, the intracoronary injection of nitroglycerin. However, our experience shows that intracoronary injection of nifedipine in a 0.2 mg dose can also have beneficial effects in these circumstances. Patients with Prinzmetal's angina who have fixed atherosclerotic lesions with superimposed spasm appear to benefit from coronary arterial bypass grafting, provided that the latter is combined with measures to treat spasm. In our experience, treatment of spasm can be achieved by partial denervation of the heart. Complementary therapy with nifedipine after coronary bypass grafting may be a useful approach, but the effectiveness of this combination of therapeutic modalities must be confirmed by a carefully performed study.

Calcium antagonists constitute the best therapy currently available for patients with Prinzmetal's angina with angiographically normal coronary arteries. Nifedipine was effective in 75 to 85 percent of these patients, as documented by the suppression of attacks, absence of signs of S-T segment changes during continuous electrocardiographic monitoring, and negative provocative tests for spasm. Nevertheless, our preliminary results must be regarded with caution, in view of the considerable spontaneous variability of symptoms in these patients, which accounts for the difficulty in evaluating therapeutic effectiveness in Prinzmetal's angina.

Montreal, Quebec, Canada

A subgroup of 22 patients with variant angina who had responded well to calcium antagonist drugs were studied to determine if ergonovine testing could help assess the need for continued therapy. Before treatment all 22 patients exhibited angina with S-T elevation during ergonovine testing done in the coronary care unit according to a previously described protocol with sequential ergonovine doses of 0.0125, 0.025, 0.05, 0.1, 0.2, 0.3 and 0.4 mg administered at 5 minute intervals. After 9.4 ± 4.7 (range 1 to 24) months of treatment (nifedipine 7 patients, diltiazem 3, verapamil 8, perhexiline 3, nifedipine and diltiazem 1), all patients were free from anginal attacks. Medication was discontinued and ergonovine testing repeated 24 to 48 hours later (3 weeks for perhexiline). In 12 of the 22 patients, angina or S-T segment shifts did not occur during the second ergonovine test to a maximal dose of 0.4 mg. Treatment was not restarted in these patients and all 12 remain free of variant anginal attacks 4.2 ± 2.9 (range 1 to 13) months later. In seven patients angina and S-T elevation occurred during the second ergonovine test, in the same electrocardiographic leads as during the test before treatment. In three patients the ergonovine test induced angina with S-T depression in the leads where S-T elevation had occurred during the previous test. Treatment was reinstituted in these 10 patients with a positive test. No complications resulted from ergonovine testing in any patient.

We conclude that in many patients with variant angina, symptoms will disappear spontaneously and the ergonovine test will revert to negative. Treatment with calcium antagonist drugs can probably be safely discontinued in some patients with variant angina; ergonovine testing appears to be helpful in identifying such patients. Longer periods of follow-up are required to confirm that symptoms do not recur.

The natural history of variant angina has not been completely defined; however, Prinzmetal et al.[1] in their original description and others[2] have recognized that many patients eventually become asymptomatic for no apparent reason. This feature of the syndrome complicates the evaluation of any therapeutic intervention. Nevertheless, variant anginal episodes usually disappear in patients treated with calcium antagonist drugs[3–8] and do not recur during continued long-term treatment. After long asymptomatic periods of drug therapy, can calcium antagonists be safely discontinued in such patients? This question is particularly pertinent to patients who manifest adverse effects from calcium antagonist drugs; although treatment with nifedipine, diltiazem or verapamil is almost always well tolerated, perhexiline induces adverse effects in many cases during prolonged treatment.[5]

In our clinical experience we have attempted to taper and discontinue calcium antagonist therapy both in patients who manifest important adverse effects and in those who remain asymptomatic after many

months or years of treatment. Attacks of variant angina do not recur in the majority of these patients and, when they do, reinstitution of treatment usually controls symptoms without permanent sequelae. However, in at least two of our patients acute myocardial infarction occurred soon after treatment with calcium antagonist drugs was decreased or discontinued.[9]

We therefore undertook this study in subsequent patients to determine whether ergonovine testing could provide useful data to assess the risk of discontinuing treatment with calcium antagonists in asymptomatic patients with previously active variant angina. Our previous studies[10] have shown that ergonovine testing can be safely performed in a coronary care unit environment with a high sensitivity in patients with active variant angina[10] and that the results of ergonovine testing during treatment with calcium antagonists correlate with the short-term clinical response to treatment.[7,11,12] The subgroup of patients selected for this study does not represent all patients with variant angina because only those who responded well to drug treatment are included.

* Numbers refer to percent luminal stenosis of each coronary vessel. † Coronary bypass graft to artery.
D = diltiazem; F = lead aVF; L = lead aVL; LAD = left anterior descending coronary artery; LCx = left circumflex coronary artery; N = nifedipine; P = perhexiline; RCA = right coronary artery; SD = standard deviation; ST↑ and ST↓ = S–T segment elevation and depression; V = verapamil.

Methods

Study patients and treatment protocol: For the purposes of this study the diagnosis of variant angina was accepted in patients who exhibited short episodes of myocardial ischemic pain at rest associated with transient S-T segment elevation, reversible with nitroglycerin, in the absence of evidence of myocardial necrosis. Each of the 22 patients in this study had previously been hospitalized in the coronary care unit for a control ergonovine test followed by at least one drug treatment period including a second ergonovine test. The study protocol followed by the patients has been described in detail elsewhere.[7,11,12]

The dose levels of the oral calcium antagonist drugs used for treatment were those that in our experience optimally combine satisfactory efficacy with infrequent adverse effects: nifedipine, 20 mg every 6 hours; diltiazem, 120 mg every 8 hours; verapamil, 160 mg every 8 hours and perhexiline, 300 or 400 mg twice daily. In Patient 20 (Table I), the dose of verapamil was only 80 mg every 8 hours because sinus bradycardia and a junctional escape rhythm at 40 to 50/min were noted at higher dose levels. In Patient 3, variant anginal attacks could not be controlled with nifedipine, diltiazem or verapamil alone but disappeared with a combination of diltiazem, 120 mg every 8 hours; nifedipine, 30 mg every 6 hours; and nitrates.[13]

After hospital discharge, all but two patients were treated with one of the calcium antagonist drugs to which they had responded in the hospital (Table I). These two patients (Cases 4 and 5) showed clinical improvement and had negative ergonovine tests while taking nifedipine,[7] but were treated with perhexiline after hospital discharge because of a temporary shortage of nifedipine. All patients returned at regular intervals after discharge to be examined by one of us. Prophylactic treatment with nitrates was not routinely employed, except in Patient 3 as previously noted.

In 18 of the 22 patients, no episodes of angina at rest occurred after hospital discharge. In the other four (Cases 7, 17, 21 and 22), brief periods of chest pain at rest compatible with variant anginal episodes occurred infrequently, less than once a week, but without documentation of coexistent S-T segment changes. Because either the beneficial effect of drug treatment or a coincident spontaneous disappearance of variant anginal attacks could account for the clinical state of the patients, each was reassessed using ergonovine testing. In one patient (Case 12) the duration of treatment was only 1 month because of the appearance of adverse effects thought to be drug-related.

Ergonovine test procedure: All ergonovine tests were performed in an identical fashion according to a protocol described in detail elsewhere.[10,12] Cuff blood pressure and a 12 lead electrocardiogram were recorded at 1 minute intervals, beginning 2 minutes before the first drug dose and continuing for a minimum of 5 minutes after the last injection. At 5 minute intervals a bolus dose of ergonovine was administered intravenously in the following sequence: 0.0125, 0.025, 0.05, 0.1, 0.2, 0.3, and 0.4 mg. An intravenous bolus dose of 0.3 mg of nitroglycerin was injected as soon as there was an S-T segment shift of 1 mm or more from the control tracing. The test was considered negative if no S-T segment shift occurred up to the final ergonovine dose of 0.4 mg.

The sensitivity of this test procedure and the incidence of complications in our initial series of patients have previously been reported.[10] To date, 75 of the 77 patients with active variant angina who underwent ergonovine testing with this protocol manifested S-T segment elevation during the test. To determine whether the results of this ergonovine test procedure are reproducible, nine patients with active variant angina underwent a second test while taking no medication within 7 days of the original test; all nine exhibited angina and S-T elevation at the ergonovine dose identical or adjacent to that of the first test.[12]

No serious complications were noted in the original descriptions[14–16] of ergonovine administration as a diagnostic test during coronary arteriography; however, three deaths were subsequently reported.[17] No complications occurred as a result of ergonovine testing in the present study. Our total experience to date using this ergonovine test protocol comprises 171 positive and 297 negative tests. Death, transmural myocardial infarction, ventricular fibrillation, complete atrioventricular block or ventricular arrhythmias requiring antiarrhythmic drug therapy did not occur during or after any of these tests.

Testing protocol: Patients to be retested without nifedipine, diltiazem or verapamil after periods of outpatient treatment were instructed to discontinue the drug 24 to 48 hours before the time of the ergonovine test. In the three patients taking perhexiline, administration of the drug was stopped 3 weeks before the test. All patients were told to return to their regular drug regimen before the ergonovine test, if they experienced chest pain after discontinuing treatment with the drug, but angina did not occur in any patient. Patients returned to the hospital where the ergonovine test in the absence of drug treatment was carried out in the morning. If the test was negative (Cases 1 to 12) the patient was discharged that afternoon and did not resume drug treatment. In 10 patients (Cases 13 to 22) S-T segment abnormalities developed. In these patients a single dose of the patients' calcium antagonist drug was given and another ergonovine test was performed 90 minutes later, during the afternoon. After the latter test, the patient was discharged with continued treatment with a calcium antagonist drug. Eight of these 10 patients were retested with the same drug and dose they had previously taken; in Patient 19 the tested drug was changed to diltiazem because of a temporary shortage of nifedipine, and in Patient 21 the drug was changed from nifedipine to diltiazem because of occasional symptoms compatible with variant anginal attacks during preceding nifedipine treatment. After these studies all patients continued to return at regular intervals to be interviewed and examined by one of us.

Coronary arteriography: All patients had undergone coronary arteriography and left ventriculography before their first ergonovine test. Selective coronary arteriography was performed with use of a percutaneous femoral approach and preformed catheters, as previously described.[18] Particular care was taken to avoid catheter-induced coronary arterial spasm. No attempt was made during cardiac catheterization to induce coronary spasm by administering ergonovine. Nitroglycerin was not given before the initial injections; however, when a lesion was noted, the vessel was filmed again in several views after administration of sublingual nitroglycerin. The left ventricular angiogram was filmed in the 30° right anterior oblique view before coronary arteriography. All angiographic documents were routinely interpreted independently by an experienced cardiovascular radiologist. The coronary arteriographic findings are listed in Table I. On left ventriculography, Patient 16 had anterolateral and apical hypokinesia, Patient 11 had diffuse hypokinesia and Patient 15 had anterolateral akinesia; the other 19 patients had normal left ventricular angiographic findings.

Results

Ergonovine test before and during drug treatment: During the control ergonovine test before treatment all 22 study patients manifested angina and S-T elevation. In 15 of the 22, the S-T elevation occurred at an ergonovine dose of 0.1 mg or less (Table I). During the same hospitalization within a drug treatment period lasting several days, the ergonovine test became negative to the maximal dose of 0.4 mg in 14 of the 22 patients. In seven of the remaining eight patients the ergonovine test remained positive with S-T elevation, but only at the dose level of 0.2 mg or higher. In five of the eight patients whose test remained positive during the drug treatment period an ergonovine dose at least two levels higher than that during the control test was required to induce a positive response.

After hospital discharge episodes of variant angina could not be detected in 18 of the 22 patients; 4 patients (Cases 7, 17, 21 and 22) had infrequent episodes of chest pain at rest, less than 1/week. Because of this favorable evolution, all 22 patients underwent another ergonovine test without drug treatment to evaluate the need for continued drug therapy.

Repeated ergonovine test without drug treatment: In 12 of the 22 patients this repeated ergonovine test induced no S-T segment shifts up to the maximal ergonovine dose of 0.4 mg. In a further seven cases, angina and S-T elevation occurred during this test, always in the same electrocardiographic leads as during the original control ergonovine test before the start of treatment. The dose of ergonovine that induced S-T elevation was the same as that of the initial test in two cases and larger in the other five. In the remaining three patients the repeated ergonovine test without drug treatment induced angina with S-T segment depression in the leads that had shown S-T elevation during the initial ergonovine test. In each of these three cases the ergonovine dose required to cause S-T depression was larger than the dose required to induce S-T elevation in the original test.

The patients whose tests reverted to negative could not be differentiated by other clinical variables from those whose tests remained positive. The mean age (± standard deviation) of those with a negative test (49.2 ± 9.1 years), was similar to those with a positive test (49.1 ± 9.1 years). Patients with normal coronary arteriograms were equally distributed between the two groups (Table I). The test reverted to negative in 7 of 9 women but only 5 of 13 men (difference not statistically significant). The duration of treatment (9.9 ± 5.4 months) in patients with a negative test was similar to that of the group with a positive test (8.6 ± 3.4 months).

Follow-up: The 12 patients whose ergonovine test reverted to negative after discontinuation of drug treatment were not restarted on calcium antagonist drug therapy. Variant angina has not recurred in any of them after a mean follow-up period of 4.2 ± 2.9 months (range 1 to 13). One patient (Case 6) has mild, stable exertional angina.

The seven patients who exhibited angina with S-T elevation during the repeated test in the absence of drug treatment underwent a second test on the same day, 90 minutes after a dose of nifedipine, diltiazem or verapamil (Table I). Each of these tests with treatment was negative up to the maximal ergonovine dose of 0.4 mg. The three patients who exhibited angina with S-T depression during the repeated test after withdrawal of drug treatment were retested in a similar fashion. However, angina with S-T depression recurred in two of these three patients during the repeated ergonovine test with treatment.

Treatment with nifedipine, diltiazem or verapamil was continued in each of the 10 patients who had S-T segment shifts during the test without drug treatment. After a mean follow-up period of 4.8 ± 3.2 months (range 1 to 14) nine patients are entirely asymptomatic. Patient 22 continues to have infrequent episodes of pain at rest, as before, but without documented S-T changes.

Discussion

Role of ergonovine testing in variant angina: The administration of ergonovine during coronary arteriography has been shown to be a sensitive and specific diagnostic test for variant angina.[14–16] In patients with documented variant angina ergonovine almost always induces angina with S-T segment elevation.[14–16] If coronary arteriography is repeated while these findings are present, severe coronary spasm is invariably found.[14–16] Because the actual visualization of coronary spasm is usually unnecessary, ergonovine testing could theoretically be performed at a time other than during coronary arteriography. The feasibility and safety of ergonovine testing done in the coronary care unit according to a carefully defined protocol using small initial doses has been demonstrated.[10] With use of this protocol, the sensitivity of the test for the diagnosis of variant angina is high and the results of the test are reproducible.[10–12]

After the start of treatment with nifedipine,[7,11,12] diltiazem[11,12] or verapamil,[11,12] the ergonovine test in nearly all patients with variant angina is either negative, or positive at a higher ergonovine dose level than during the test before treatment. During short treatment periods lasting several days, the results of ergonovine testing correlate with the clinical state; that is, patients with a negative test or a test positive only at the dose level of 0.3 or 0.4 mg of ergonovine have infrequent variant anginal episodes or none at all, but patients with a test still positive at small doses of ergonovine usually continue to have frequent attacks.[7,12]

Role of ergonovine testing in determining when to discontinue treatment: These considerations suggest that the results of ergonovine testing might be useful in determining when to discontinue calcium antagonist drug therapy in asymptomatic patients with variant angina. Each of the patients in this study manifested angina with S-T elevation during the ergonovine test before treatment; in 14 of the 22, the re-

peated test at the start of treatment was negative. When the patients were restudied after an average follow-up period of 9 months, the ergonovine test performed in the absence of medication was negative in 12 cases. Treatment was not restarted in these patients and variant angina has not recurred over a subsequent follow-up period averaging 4 months. Thus, a negative ergonovine test appears to correlate with the absence of variant anginal attacks not only during drug treatment periods but also after treatment is stopped.

Longer follow-up periods are necessary to confirm that discontinuing administration of calcium antagonist drugs in these patients in this manner is entirely safe. The clinical course of variant angina is often characterized by abrupt variations in the frequency of symptoms, suggesting that variant anginal attacks might eventually recur in some of these patients.

Significance of S-T depression during ergonovine test: Of the remaining 10 patients who were retested after discontinuation of treatment, 7 manifested angina with S-T elevation as they had during their initial ergonovine test before treatment. However, the other three patients exhibited S-T depression in the same electrocardiographic leads in which S-T elevation had occurred during their first ergonovine test. Maseri et al.[19] have described S-T depression caused by coronary spasm in patients who at other times spontaneously demonstrated S-T elevation. In our experience nearly 100 percent of patients with active variant angina who have undergone ergonovine testing have exhibited S-T elevation during the test. The occurrence of S-T depression during the test likely represents a less severe degree of coronary spasm than would be present with S-T elevation. Stein et al.[20] described S-T depression after ergonovine administration in patients with coronary disease without variant angina; these findings may have been caused by the normal physiologic effect of ergonovine on peripheral and coronary resistance and not by focal coronary spasm. However, spasm probably caused the S-T depression in at least two of the three patients in our study because they did not have significant fixed coronary stenoses.

Significance of disappearance of symptoms after treatment: Do asymptomatic patients with a negative ergonovine test in the absence of medication still have variant angina? It is customary to think of variant angina as a permanent diagnosis and not as a transient phenomenon; however, as originally noted by Prinzmetal et al.,[1] symptoms often disappear entirely, particularly if myocardial infarction occurs. Although the clinical manifestations of variant angina are known to be caused by coronary arterial spasm, the mechanisms that induce spontaneous episodes of coronary spasm are unclear. Until the etiology of variant angina is better understood or until long-term follow-up studies of large numbers of patients are completed, the exact status of asymptomatic patients who previously had variant angina will remain unclarified.

From a practical point of view, the results of our study suggest that many patients with variant angina who are asymptomatic during long periods of treatment with calcium antagonist drugs may not require further therapy. Ergonovine testing appears to be an objective method of evaluating the clinical status of patients with variant angina.

Acknowledgment

We thank the nurses of our coronary care unit for their skillful care of these patients, Margot Méthé, RN for superb technical assistance, the physicians who referred the patients to us for study and Luce Bégin and Diane Asselin-Roy for preparing the manuscript.

Facts your patient can live with.

Just as heart patients depend on your diagnostic judgement to maintain healthy lives, your diagnosis and treatment depend on reliable information.

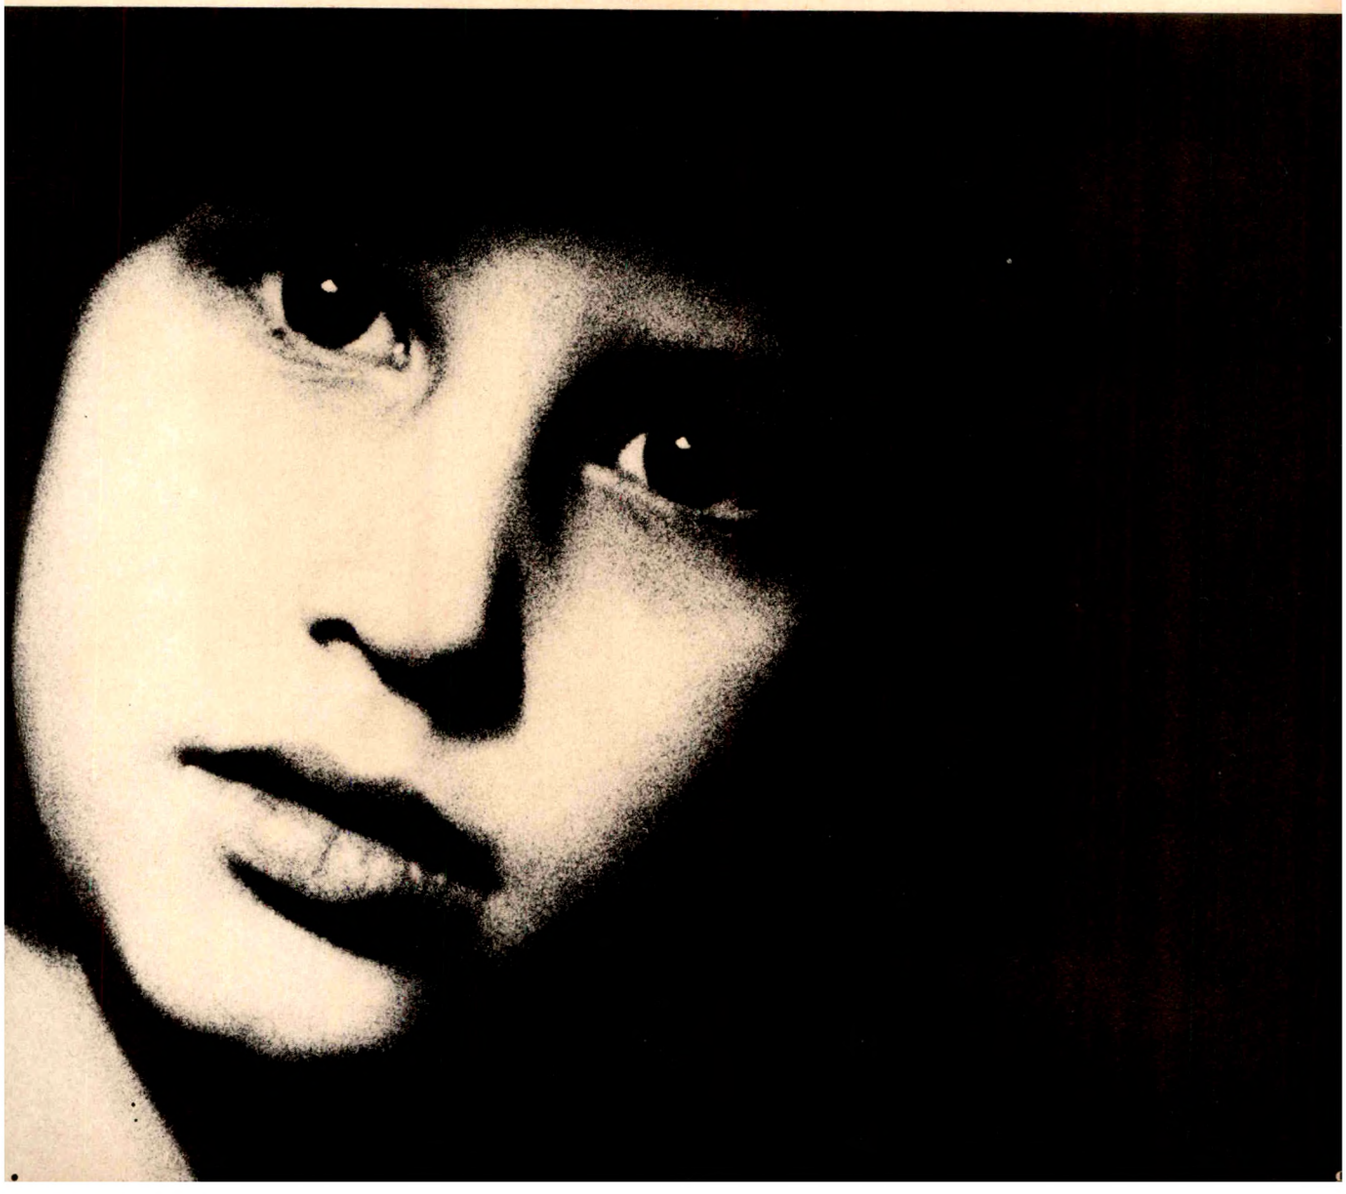
Yet results from an important test, ambulatory ECG recording and scanning, are not always reliable. Current ambulatory-type scanning systems demand tedious, undivided concentration. Fatigue is unavoidable.

Datamedix is solving the problem. Through the efforts of doctors, scientists and engineers, Datamedix has developed a system to provide accurate ambulatory monitoring at a fraction of the time and cost of existing systems.

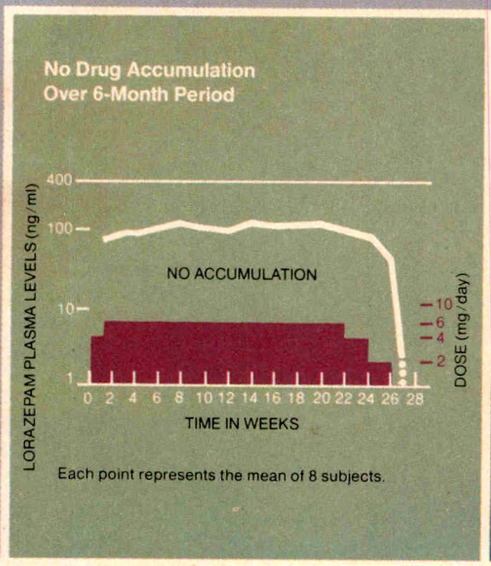
It's called PECGASYS™, Programmable Electrocardiographic Analysis System. Your patient wears the Ambulatory Monitoring Unit for any period up to 24 hours. Then, within minutes of the patient's return to your office, PECGASYS generates a full report, in plain English, with supportive graphs, morphology, rhythm strips and other data. No tapes. No waiting for a technician's report. No scanning error. Your analysis is delivered with greater speed, accuracy and flexibility than ever before possible.

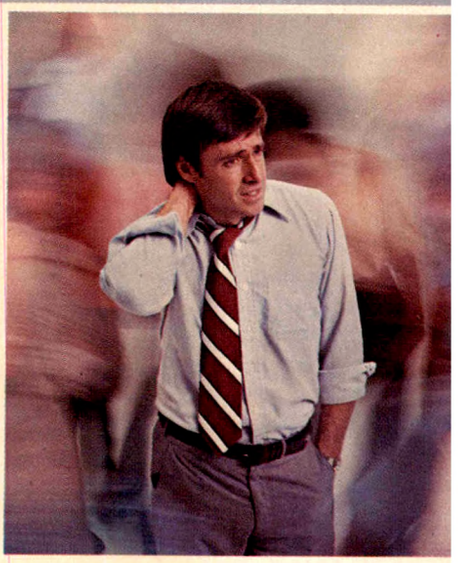
PECGASYS is resetting the limits on the speed and accuracy of ambulatory ECG analysis. To get your PECGASYS brochure, write to Datamedix, Arvida Park of Commerce, 1001 NW 58th St., Boca Raton, FL 33431.

DATAMEDIX



How do you choose a minor tranquilizer?





Wyeth Laboratories
Philadelphia, PA 19101
TM

Pharmacokinetics

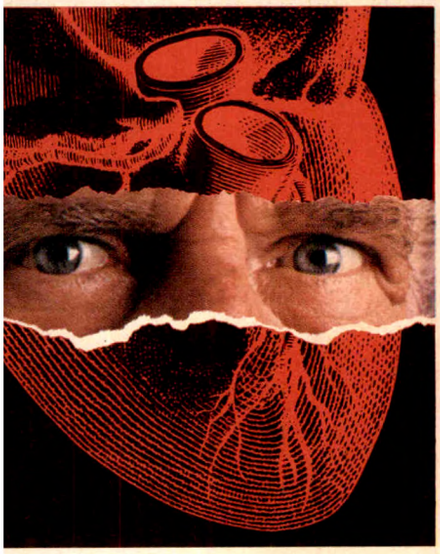
Ativan (lorazepam) is eliminated more rapidly than other benzodiazepines; generates no clinically active metabolites. The half-life of free lorazepam is about 12 hours; steady-state blood levels are attained in 2-3 days. (Comparable data for diazepam: 20-50 hours and at least 7-10 days.) Ativan shows no evidence of accumulation, even when given in high doses for as long as 6 months. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Anxiety neuroses

In many nationwide studies involving thousands of patients with anxiety neuroses, Ativan (lorazepam) consistently provided significant relief of anxiety, tension, agitation and irritability as measured by standard Hamilton, Global (physician rated) and 35-Item (patient self-rated) scales.

They're all about the same, aren't they? Until recently, that seemed to sum up the prevalent attitude about the benzodiazepines. After all, they all work similarly and all are effective anxiolytics. With seven of these compounds now available, however, differences have begun to emerge. Foremost among them: different metabolic pathways, which distinguish the relatively short-acting Ativan (lorazepam) from long-acting diazepam, clorazepate and chlordiazepoxide. At the same time, your choice can be made with confidence in the clinical record of Ativan, which confirms its value in anxiety neuroses and in significant anxiety associated with functional or organic disorders, as well as in older patients.

Consider the record of Ativan:



Anxiety in cardiovascular disorders

Ativan (lorazepam) has been specifically evaluated and found effective in seven common protocol, double-blind studies involving 423 patients (211 on Ativan) whose anxiety was related to organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in gastrointestinal disorders

So far, nine common protocol, double-blind studies of Ativan have focused on anxious patients with functional or organic gastrointestinal complaints (457 patients, 234 on Ativan). Ativan was clearly effective in reducing the anxiety of these patients. The gastrointestinal component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in the aging patient

Because its simple metabolism is not readily impaired with advancing age, and accumulation is not likely to present a problem, Ativan is a good choice for older patients. Those who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

Ativan® (lorazepam) for Anxiety

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® (IV) for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Nitrol®
(nitroglycerin ointment, 2%)

Description: Nitrol® Ointment contains 2% nitroglycerin (glyceryl trinitrate) in a special lanolin-petrolatum base. It is a prompt acting vasodilator, effective in the relief and prevention of anginal attacks.

Action: When the ointment is spread on the skin, the active ingredient (nitroglycerin) is continuously absorbed through the skin into the circulation, thus exerting prolonged vasodilator effect. Nitroglycerin ointment is effective in the control of angina pectoris, regardless of the site of application.

Indications: Prevention and treatment of angina pectoris attacks.

Contraindications: May be contraindicated in patients with marked anemia, increased intraocular pressure or increased intracranial pressure. Should not be employed in patients with known idiosyncrasies to nitrites.

Warning: In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

Precautions: A hypotensive headache is a sign of overdosage. Occasionally elderly patients may have no untoward symptoms while recumbent but may develop postural hypotension with faintness upon suddenly arising.

Dosage and Administration: For angina pectoris the ointment may be applied every 3 to 4 hours as required. The usual dose is 1 to 2 inches, as squeezed from the tube, although some patients may require as much as 4 or 5 inches. The ointment should be spread in a thin uniform layer on the skin. The optimum dosage is determined by starting with an application of ½ inch of ointment and increasing the dose in ½ inch increments each successive application until headache occurs, then decreasing to the largest dose which does not cause headache. Nitrol Ointment can be applied to any convenient skin area but psychologically, many patients prefer the chest.

Measurement and application of the ointment is easily accomplished with the aid of the specially designed Appli-Ruler™ supplied with the ointment. The ointment can be squeezed onto the graduated area of the Appli-Ruler and conveniently spread over the desired skin area. Keep the tube tightly closed and store at controlled room temperatures.

Caution: Federal law prohibits dispensing without prescription.

Supplied:
30 gram tube NDC 0091-5617-31
60 gram tube NDC 0091-5617-02
30 gram 6-Pack Unit NDC 0091-5617-61
60 gram 6-Pack Unit NDC 0091-5617-62

The Original...
Nitrol® (nitroglycerin ointment, 2%)
Fills a therapeutic void
in your cardiology practice
Nitrol Ointment—the original topical coronary vasodilator—provides subjective symptomatic improvement for your angina patients; long-lasting freedom from pain and discomfort; possible reduction in oral medication requirements; decreased nocturnal attacks; overall symptomatic improvement.
The clinical efficacy of Nitrol has been confirmed in 12 published studies.
• supplements sublingual nitroglycerin medication
• provides consistently prolonged beneficial hemodynamic effects[1,4]
• produces sustained, enhanced exercise capacity; concomitant changes in heart rate and blood pressure—without evidence of tolerance or toxicity[1]
• decreases pulmonary wedge and arterial pressures plus systemic diastolic arterial pressures up to 5 hours[2]
• favorably affects peripheral vascular resistance, venous capacitance, preload and afterload[3,4]

Interrogatabl

6 3

Programalith 6 is the full six-parameter interrogatable, programmable pacemaker. In conjunction with the Programmer, Programalith 6 provides the physician with the means for comprehensive paced-patient management while obviating many common reasons for invasive pacing system revision.

For less critical applications, Programalith 3 provides the physician with the same basic interrogation capabilities as Programalith 6 as well as three programming functions – pacing rate, pulse width and sensitivity – all wit multiple options.

Only after you have reached the ultimate in sophistication can you truly simpli This new 6-3-1-0 family of Programalith® Interrogatable™ pacemakers is id demonstration of that fact. It is the most flexible system ever offered the physicia Even the simplest of these four pulse generators offers the all-important Paceset exclusive: a simple method of calculating years of remaining battery capac as well as an accurate determination of possible problems and their locati through measurement by interrogation of lead and heart interface impedan

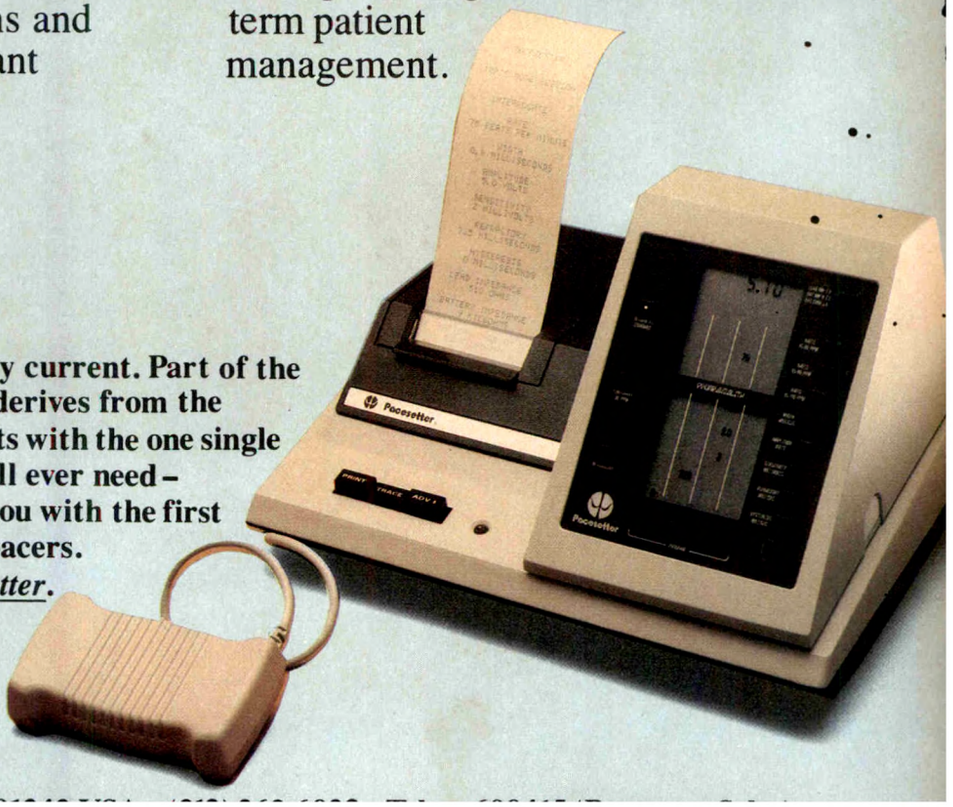
Pacesetter® Sustems, I

a Complete Family of Pacemakers.

Programalith 1 interrogates and programs a single parameter – pacing rate – allowing the physician to choose from 12 different options and provides the all-important interrogation function as well.

For simplest applications, Programalith 0 requires no programming, yet can still be interrogated for all measured data, providing invaluable assistance in long term patient management.

ttery impedance and battery current. Part of the exibility of this new system derives from the mplete integration of all units with the one single rogrammer the physician will ever need – e one Pacesetter supplies to you with the first nplant of any one of these pacers. o wonder they call us Pace*setter*.



Together... we provide a clearer view of human anatomy and physiology.

As specialists in the field of diagnostic medicine, Technicare recognizes the advantage to having more than one point of view. For this reason Ohio Nuclear and Unirad have combined their special strengths in three of the most important diagnostic imaging fields. Now under the name of Technicare, we are dedicated to further exploring, expanding and developing our resources and as a subsidiary of the Johnson & Johnson Company, we are more effectively meeting the individual needs of our customers, capability, providing products and services that enhance their diagnostic potential. Having expanded our in Computed Tomography, Nuclear Medicine and Ultrasound. With greater diversified view to meet the needs of today, we are better prepared to meet the needs of tomorrow as well.

potassium chloride slow-release tablets 8 mEq

Please turn page for brief prescribing information.

CIBA

SLOW-K®
potassium chloride slow-release tablets

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.

2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.

3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
In patients with hyperkalemia, since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium.

All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the G.I. tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium intravenously but may also occur when given orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. Use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
Potassium depletion is ordinarily diagnosed by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. Treatment of potassium depletion, particularly in presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, electrocardiogram, and clinical status of patient.

ADVERSE REACTIONS
Most common to oral potassium salts: nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

One of the most severe adverse effects is hyperkalemia (see Contraindications and Warnings). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
Usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires loss of 200 or more mEq of potassium from the total body store.

Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for prevention of hypokalemia to 40-100 mEq per day or more for treatment of potassium depletion.

Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

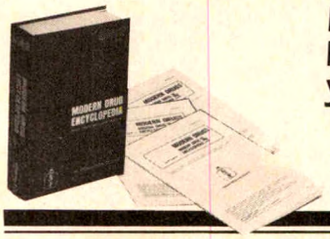
How thorough and unbiased is your drug reference?



If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 15th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 15th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:
- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main secton as follows:
- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

And, our Free Updating Service informs you of changes in specifications and introduces new drugs. These periodic supplements adopt the same easy-to-read format of the basic volume. You receive them free of charge until the publication of the next (16th) Edition.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

The Frustrated Benevolence of "Dr. Anonymous"

PAUL KLIGFIELD, MD

New York, New York

Shortly after William Heberden published his original description of the clinical features of angina pectoris in 1772, he received an intriguing letter from an unnamed physician who suffered from the disease. The case of "Dr. Anonymous" is significant as the earliest account of ischemic heart disease clearly associated with ventricular arrhythmias. This astute observer not only predicted his own sudden death, but also offered his body in the benevolent hope that autopsy correlation would contribute to the understanding of the cause of angina pectoris.

The association of ventricular arrhythmias with sudden death in the setting of ischemic heart disease is currently well appreciated. Although many patients are aware of their cardiac rhythm irregularities, few describe their symptoms and occasional sense of impending doom as colorfully as did "Dr. Anonymous," an unnamed 18th century English physician who in 1772 recognized his own angina pectoris from reading Heberden's original account of the disease. The events surrounding this intriguing case of "Dr. Anonymous," who predicted his own sudden death, are an important and revealing chapter in the early history of knowledge of angina pectoris. This physician both provided us with one of the earliest clinical descriptions of ischemic arrhythmia and offered his own body for autopsy examination in the hope that a pathologic basis for the disease could be established.

More than 2 centuries ago, William Heberden of London (Fig. 1) introduced the original, masterful clinical description of angina pectoris in the second volume of the *Medical Transactions*.[1] "Some account of a disorder of the breast" was published in 1772, based on 20 cases presented to the College of Physicians in 1768, and later expanded by an additional 80 cases as a chapter in his *Commentaries on the history and cure of diseases* which appeared posthumously in 1802.[2]

Heberden received his medical degree at Cambridge in 1739 and became a highly successful London practitioner. Fluent in Latin, Greek and Hebrew, he was described by his illustrious patient Samuel Johnson as "ultimum Romanorum, the last of our learned physicians." In addition to his clinical account of angina, Heberden is known for his early descriptions of deforming arthritis of the hands, night blindness and varicella. In 1759 he collaborated with Benjamin Franklin in preparing a pamphlet on inoculation for use in the Colonies.

Heberden's description of angina pectoris clearly outlined the classic symptoms[1]:

> Those, who are afflicted with it, are seized, while they are walking, and more particularly when they walk soon after eating, with a painful and most disagreeable sensation in the breast, which seems as if it would take their life away, if it were to increase or to continue: the moment they stand still, all this uneasiness vanishes . . . After it has continued some months, it will not cease so instantaneously upon standing still; and it will come on, not only when the persons are walking, but when they are lying down and oblige them to rise up out of their beds every night for many months together: and in one or two very inveterate cases it has been brought on by the motion of a

From the Division of Cardiology, Department of Medicine, The New York Hospital-Cornell Medical Center, New York, New York. Manuscript received July 8, 1980, accepted July 30, 1980.

Address for reprints: Paul Kligfield, MD, Division of Cardiology, The New York Hospital-Cornell Medical Center, 525 East 68th Street, New York, New York 10021.

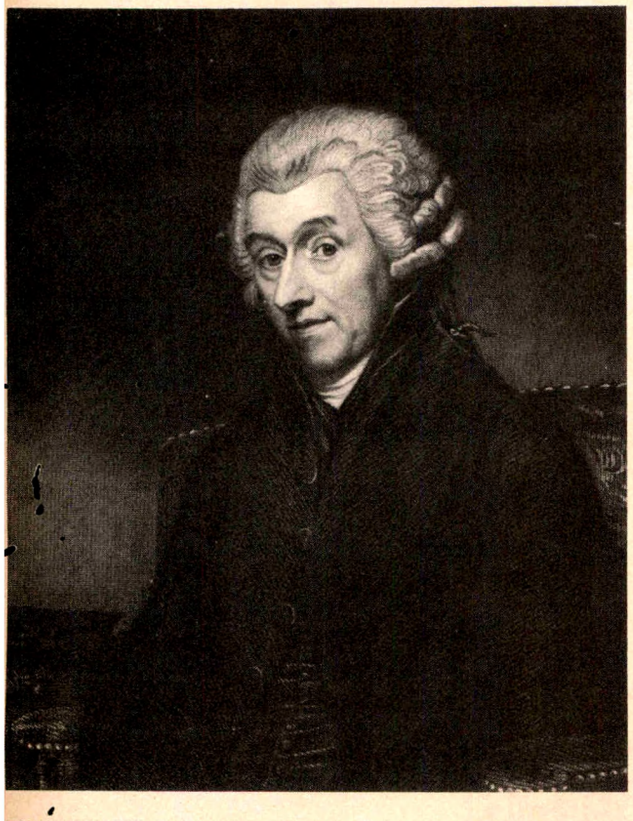

FIGURE 1. William Heberden, whose 1772 original description of angina pectoris prompted "Dr. Anonymous" to report his own intriguing case. After a portrait by Beechey.

horse or a carriage, and even by swallowing, coughing, going to stool or speaking, or by any disturbance of mind . . . .

Heberden was careful to make no unverified speculation regarding the origin of angina: "What the particular mischief is," he observed, "is not easy to guess, and I have had no opportunity of knowing with certainty." He was clearly aware of sudden death among patients with the disorder but had been unable to observe an autopsy. The reason, he explained, was that "most of those, with whose cases I had been acquainted, were buried, before I had heard that they were dead."

In April of 1772, shortly after publication of this account, Heberden received a letter from an anonymous English physician[3]: "I am now in the fifty-second year of my age," the writer explained by way of introduction, "of a middling size, a strong constitution, a short neck, and rather inclining to be fat." Regarding Heberden's recent description, he observed, "I found it to exactly correspond with what I have experienced of late years."

There is little doubt that this physician suffered from angina pectoris. "The first symptom is a pretty full pain in my left arm a little above the elbow," he noted, "and in perhaps half a minute it spreads across the left side of my breast, and produces either a little faintness, or a thickness in my breathing; at least I imagined so, but the pain generally obliges me to stop." Symptoms were precipitated by effort but never at rest. "It always attacked me when walking, and always after dinner," but never "in a morning, nor when sitting, nor in bed."

What made his case unusual, "Dr. Anonymous" informed Heberden, was associated sensations that "have frequently led me to think that I should meet with a sudden death." These symptoms, from a modern vantage point, must certainly have been caused by recurrent ventricular arrhythmias. "I have often felt," he wrote, "what I can best express by calling it an universal pause within me of the operations of nature for perhaps three or four seconds; and when she has resumed her functions, I felt a shock at the heart, like that which one would feel from a small weight being fastened by a string to some part of the body, and falling from the table to within a few inches of the floor." This vivid description suggests perception of the enhanced ejection that results from postextrasystolic potentiation after single or sequential ventricular ectopic complexes.

Convinced by this disturbing sensation that his death was imminent, "Dr. Anonymous" offered his body for examination and pathologic correlation under Heberden's supervision, hoping to "shew the cause of it; and, perhaps, tend at the same time to a discovery of the origin of that disorder, which is the subject of this letter, and be productive of means to counteract and remove it." As occasionally happens, this intimation of impending death was soon realized. The death of "Dr. Anonymous" within a half hour of the onset of symptoms occurred during an after-dinner walk. According to Heberden, "by a paper found in his will, if he died suddenly, he had desired that I might immediately have notice of it, in order to have the body opened and examined."

The autopsy was performed within 48 hours. Heberden's appreciation for the potential posthumous contribution of "Dr. Anonymous" to the understanding of angina is apparent. "I used my best endeavors," he reported, "that such a benevolent intention should not be frustrated, by procuring that experienced and accurate anatomist Mr. J. Hunter to open the body." John Hunter, then recently appointed surgeon to St. George's Hospital, was assisted in this examination by his pupil Edward Jenner.

Both the anonymous letter to Heberden and Hunter's postmortem findings were published in the third volume of the *Medical Transactions*.[3] Despite careful attention to the chest, Heberden noted that "no manifest cause of his death could be discovered." Although no abnormalities of the heart were found at the time, Jenner later reported to Caleb Hillier Parry[4] that the coronary arteries in this early important case of angina were not carefully examined. Thus, the benevolent intention of "Dr. Anonymous" that his death would provide direct insight into the underlying cause of angina pectoris was indeed frustrated. Yet his letter served to focus clinical attention on the need for clinical-pathologic correlation. Subsequent cases, involving Jenner

as investigator and Hunter as both investigator and victim of the disease, soon established the association with obstructive coronary lesions.[5]

Who was the astute and benevolent "Dr. Anonymous"? Recent examination of the Hunter manuscript case records by Dr. K. D. Keele[6] has identified a Dr. Haygarth of Chester as Heberden's previously unnamed correspondent. Haygarth's case is important as the earliest description of angina associated with significant cardiac arrhythmia. Further examination of the life and times of this physician, who anticipated his own sudden death from ischemic heart disease and made a noble effort to contribute to our understanding of its cause, will be of great interest.

CALENDAR OF EXTRAMURAL PROGRAMS

The aim of each program is to increase the theoretical and practical knowledge of the normal and abnormal function of the cardiovascular system in man. Most of the programs are pertinent to direct care of patients with heart disease. The need for such programs increases with the ever increasing amount of scientific and clinical data, the constant changes in technology and methodology, and the greater availability of therapeutic options. Today most cardiologists, internists and family practitioners feel the need of supplementing their professional reading by direct contact with the authors, research workers and leaders in the field.

To solve these problems the Committee selects each year series of carefully supervised programs which are usually preceded by extensive consultations with the program directors recruited among the foremost specialists educators and scientists in the field of clinical cardiology and allied basic science disciplines.

Although each program director is personally responsible for the choice of faculty, and the structure of the program, the Continuing Education Committee for Extramural Programs assumes the overall responsibility for the caliber of the postgraduate education and the relevance to the practice of cardiology. This is accomplished by the processes of meticulous scrutiny of the objectives, analysis of the educational methods, and studying the impact of each course on the knowledge and attitudes of the participants.

These programs should help each physician to keep up with the new knowledge, to put into practice the new advances and to retract gracefully from the obsolete and useless practices. An effective practitioner must learn and relearn, listen to new ideas, share past experiences and observe the work of his peers. The Continuing Education Committee for Extramural Programs of the American College of Cardiology believes that these goals can be accomplished by all members and nonmember professionals participating in our continuing education programs.

Leonard S. Dreifus, MD, FACC
Chairman, Continuing Education Committee
for Extramural Programs

Programs and faculty are subject to change. For further information write Registration Secretary, Extramural Programs Department, American College of Cardiology, Heart House, 9111 Old Georgetown Road, Bethesda, Maryland 20014.

331	June 29–30, July 1	B. Leonard Holman, MD	Nuclear Cardiology
330	July 8–10	Michael R. Rosen, MD	Clinical Pharmacology and Electrophysiology of Antiarrhythmic Drugs

INSTRUCTIONS FOR AUTHORS

The editors of THE AMERICAN JOURNAL OF CARDIOLOGY welcome concise articles devoted to cardiovascular disease. Articles must be contributed solely to THE AMERICAN JOURNAL OF CARDIOLOGY and become the property of the Publisher. The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. Authors will assist the editors in the prompt processing of manuscripts if these instructions are followed:

THE WHOLE PAPER

- Address manuscript to Managing Editor, American Journal of Cardiology, 666 Fifth Ave., New York, NY 10019.
- Submit two copies of all elements of the article: text, references, legends, tables and figures.
- Arrange the paper in this order: (1) title page; (2) abstract; (3) text; (4) references; (5) legends; (6) tables; and (7) figures.
- Number all pages in above sequence, beginning with title page as 1, abstract as 2, etc.
- Type all matter: (1) on 8½ × 11 opaque white bond paper; (2) in duplicate; (3) on one side of each sheet only; (4) double-space; (5) leave wide margins, all four sides.

THE TITLE PAGE

- Include first names, degrees and, where applicable, FACC for all authors.
- Provide a short running title of 3 to 6 words.
- Insert at bottom: name and address of institution from which work originated plus information about grants.
- Add at bottom the phrase "Address for reprints: . . ." followed by full name and address with zip code.

THE ABSTRACT

- Limit words as follows: 100 to 250 words for major articles; 50 to 100 words for case reports.
- Add at end of abstract: list of 2 to 6 key words and subjects for indexing.

THE TEXT

- Type in duplicate; double-space.
- Do not use abbreviations such as SVC, WPW: write out superior vena cava, Wolff-Parkinson-White.
- Abbreviate measurements (mm, kcal and the like) as recommended in *Uniform Requirements for Manuscripts Submitted to Biomedical Journals,* published in *Am Rev Respir Dis* 1979; 119:3–10; *Ann Intern Med* 1979; 90:95–9; *Br Med J* 1979; 1:532–5; and *Lancet* 1979:1:428–30.
- Cite in numerical order every reference, figure and table. (Order of mention in text determines the number given to each.)
- Place acknowledgments at end of text, before references.

THE REFERENCES

- Type in duplicate; double-space.
- Number the references in order in which they are mentioned in text.
- Provide concluding page numbers for all journal references and specific page numbers for all book references. Indicate all abstracts by the abbreviation (abstr).
- Follow the general arrangement, abbreviations and punctuation styles shown below.

THE FIGURE LEGENDS

- Start at top of new page.
- Type in duplicate; double-space.
- Identify at the end of each legend and in alphabetical order all abbreviations in the figure described.

THE TABLES

- Start each table at top of new page.
- Type in duplicate; double-space.
- Give each table a number (in roman numerals: Table I, II, etc) and a title. Number the tables in order in which they are mentioned in the text.
- Provide a footnote to each table—identifying in alphabetical order all abbreviations used.

THE FIGURES

- Submit 2 glossy prints (not originals) of each photo and drawing.
- Please note that art work of published articles will not be returned.
- Use black ink for all charts (line drawings) Make decimals, broken lines, etc. strong enough for reproduction.
- Use arrows to designate special features.
- Crop photomicrographs to show only essential field.
- Identify figures on back by number and author's name.
- Number figures in order in which they are mentioned in the text.
- Indicate top of each figure.
- Submit written permission from publisher and author to reproduce any previously published figures.
- Limit figures to number necessary for clarity. The publisher allows a limited sum toward reproduction.

Examples of Styles of References

For periodicals, follow INDEX MEDICUS, listing *all* authors (if there are 7 or more, list only 3 and add et al.):

31. Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–34.

(Author: please note that no periods are used after authors initials)

For chapter in book:

For books (personal author or authors):

36. Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

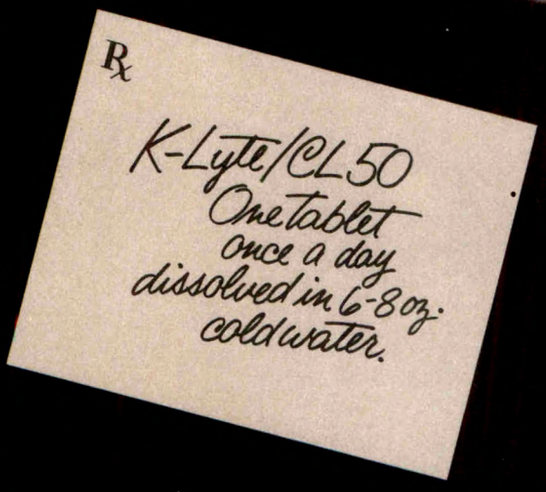
(Author: all book references should have specific page numbers.)

K-LYTE/CL® 50

Each effervescent tablet
in solution supplies
50 mEq potassium chloride

the once-a-day potassium chloride supplement

Fruit punch and citrus flavors



EFFERVESCENT TABLETS
K-LYTE/CL® 50 mEq—Fruit Punch and Citrus Flavors
(Each effervescent tablet in solution supplies 50 mEq potassium chloride)

PRESCRIBING CONSIDERATIONS

INDICATIONS: K-LYTE/CL 50 mEq is an oral potassium supplement for therapy or prophylaxis of potassium deficiency. It is particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE/CL 50 mEq may also be useful for potassium administration where digitalis intoxication results in cardiac arrhythmias.

CONTRAINDICATIONS: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

WARNINGS AND PRECAUTIONS: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosage adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

ADVERSE REACTIONS: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

DOSAGE AND ADMINISTRATION: Adults: 1 tablet completely dissolved 1 to 2 times daily, depending upon the requirements of the patient: 1 tablet (50 mEq potassium chloride) in 6 to 8 ounces of cold or ice water. The normal adult daily requirement is approximately 50 mEq of elemental potassium.
NOTE: It is suggested that K-LYTE/CL 50 mEq be taken with meals and sipped slowly over a 5-10 minute period.

HOW SUPPLIED: K-LYTE/CL 50 mEq effervescent tablets (fruit punch and citrus flavors) cartons of 30 and 100. Also available, K-LYTE/CL effervescent tablets (25 mEq fruit punch and citrus flavors) cartons of 30 and 250. Each tablet is individually foil wrapped.

INTROPIN® RESPONDS
(dopamine HCl)

MATCH CHANGING CONDITIONS IN SHOCK BY FINE-TUNING DOSAGE

tropin — at any oint time shock

other drug works like Intropin® opamine HCl) in "routing" blood ere it is needed, and when it is eded, to maintain vital organ rfusion. Careful dosage titration ovides the particular hemody- mic/renal effects you desire for given patient, at any point in e, over a wide range of shock mptoms.

nique dosage exibility... nique patient sponse

ghtly hypotensive patients h lo ut adequate cardiac out- t, fa urine output and duced vital organ perfusion ually experience increased urine w, modest increases in cardiac tput and reduced peripheral istance with low Intropin doses 5 mcg/kg/min).

derate hypotension, reduced rdiac output and venous return s further reductions in urine out- t are likely to respond to inter- ediate (5-20 mcg/kg/min) ropin doses by showing further creases in cardiac output, blood essure, vital organ perfusion d urine flow.

hen severely hypotensive tients with greatly reduced sys- mic vascular resistance, cardiac and urine output and poor perfusion are given Intropin doses of greater than 20 mcg/kg/min, the blood pressure increases (due to increases in both cardiac output and SVR) while the mild dopaminergic action on the kidney may be somewhat offset by the alpha effect.

Intropin — maintains vital organ perfusion in patients at high risk of shock

Beneficial Intropin effects result from:

- direct increase in blood flow to vital organs, due to dilation of blood vessels in the renal, coronary and mesenteric areas as well as constriction of vasculature of the skin and muscle.
- predictable increase in urine output.
- direct increase of cardiac output, primarily due to increased stroke volume.
- predictable maintenance or increase in blood pressure.

By comparison, other catecholamines (dobutamine, isoproterenol, norepinephrine) while usually favorably affecting cardiac output, may have unpredictable (or even adverse) effects on blood pressure, coronary perfusion or circulation to other vital organs. Increasing the dosage intensifies both the favorable and unfavorable actions of these drugs.

Intropin — recommended for any patient in shock due to:

- myocardial infarction
- trauma
- endotoxic septicemia
- open heart surgery
- renal failure
- congestive heart failure

Intropin dosage forms and concentrations designed for fast, convenient patient care

Please see following page for prescribing information. For furthe information, please contact Medical Services Department of American Critical Care, Division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, Illinois 60085. Phone 312-473-3000.

Division of American Hospital Supply Corporation

American Critical Care

INTROPIN (dopamine HCl)

5 ml AMPUL and SINGLE-DOSE VIAL
5 ml ADDITIVE SYRINGE (Rap-Add®)
(200 mg and 400 mg concentrations)

BRIEF SUMMARY OF PRESCRIBING INFORMATION

DESCRIPTION: INTROPIN (dopamine HCl) is 3, 4-dihydroxyphenethylamine hydrochloride, a naturally occurring biochemical-catecholamine precursor of norepinephrine. Intropin is a clear, aqueous additive solution for intravenous infusion after dilution.

INDICATIONS: For the correction of hemodynamic imbalances present in the shock syndrome due to myocardial infarctions, trauma, endotoxic septicemia, open heart surgery, renal failure, and chronic cardiac decompensation as in congestive failure.

Poor Perfusion of Vital Organs – Urine flow appears to be one of the better diagnostic signs by which adequacy of vital organ perfusion can be monitored. The physician should also observe the patient for signs of reversal of confusion or comatose condition. Loss of pallor, increase in toe temperature and/or adequacy of nail bed capillary filling may also be used as indices of adequate dosage. Note that at doses above those optimal for the individual patient, urine flow may decrease, necessitating reduction of dosage. Concurrent administration of INTROPIN and diuretic agents may produce a potentiating effect.

Low Cardiac Output – Increased cardiac output is related to the direct inotropic effect of INTROPIN on the myocardium. Increased cardiac output at low or moderate doses has been associated with either static or decreased systemic vascular resistance (SVR) and appears to be related to a favorable prognosis. Increase in cardiac output produced by INTROPIN is not associated with substantial decreases in SVR as may occur with isoproterenol.

Hypotension – Hypotension due to inadequate cardiac output can be managed by administration of low to moderate doses of INTROPIN, which have little effect on SVR. At high therapeutic doses, the drug's alpha adrenergic activity becomes more prominent and thus may correct hypotension due to diminished SVR. Administration should be considered as soon as a definite trend toward decreased systolic and diastolic pressure becomes evident.

CONTRAINDICATIONS: INTROPIN should not be used in patients with pheochromocytoma.

WARNINGS: INTROPIN should not be administered in the presence of uncorrected tachyarrhythmias or ventricular fibrillation. INTROPIN should not be added to any alkaline diluent solution since the drug is inactivated in alkaline solutions. Patients who have been treated with monamine oxidase (MAO) inhibitors prior to the administration of INTROPIN will require substantially reduced dosage (1/10 the usual starting dose).

Usage in Pregnancy – INTROPIN may be used in pregnant patients when, in the judgment of the physician, the expected benefits outweigh the potential risk to the fetus.

Usage in Children – The safety and efficacy of INTROPIN for pediatric use has not been established.

PRECAUTIONS: Avoid Hypovolemia – Prior to treatment with INTROPIN, hypovolemia should be fully corrected, if possible, with either whole blood or plasma as indicated.

Decreased Pulse Pressure – If a disproportionate rise in the diastolic pressure (i.e. a marked decrease in the pulse pressure) is observed in patients receiving INTROPIN, the infusion rate should be decreased and the patient observed carefully for further evidence of predominant vasoconstrictor activity, unless such an effect is desired.

Extravasation – INTROPIN should be infused into a large vein whenever possible to prevent the possibility of extravasation into tissue adjacent to the infusion site which may cause necrosis and sloughing of surrounding tissue. Large veins of the antecubital fossa are preferred to veins in the dorsum of the hand or ankle.

Occlusive Vascular Disease – Patients with a history of occlusive vascular disease (for example, atherosclerosis, arterial embolism, Raynaud's disease, cold injury, diabetic endarteritis, and Buerger's disease) should be closely monitored for any changes in color or temperature of the skin in the extremities.

IMPORTANT – Antidote for Peripheral Ischemia: To prevent sloughing and necrosis in ischemic areas, the area should be infiltrated as soon as possible with 10 to 15 ml of saline solution containing from 5 to 10 mg of Regitine® (brand of phentolamine), an adrenergic blocking agent. A syringe with a fine hypodermic needle should be used, and the solution liberally infiltrated throughout the ischemic area. Sympathetic blockade with phentolamine causes immediate and conspicuous local hyperemic changes if the area is infiltrated within 12 hours. Therefore, *phentolamine should be given as soon as possible* after the extravasation is noted.

Avoid Cyclopropane or Halogenated Hydrocarbon Anesthetics – Because of the theoretical arrhythmogenic potential of these agents and the known increase in cardiac autonomic irritability which may sensitize the myocardium, INTROPIN should be used with EXTREME CAUTION in patients inhaling such anesthetics.

Careful Monitoring Required – As in the case of any adrenergic agent, infusion of INTROPIN should be accompanied by close monitoring of urine flow, cardiac output and blood pressure.

ADVERSE REACTIONS: The most frequent include ectopic beats, nausea, vomiting, tachycardia, anginal pain, palpitation, dyspnea, headache, hypotension, and vasoconstriction. Others reported infrequently are aberrant conduction, bradycardia, piloerection, widened QRS complex, azotemia, and elevated blood pressure.

WARNING: This is a potent drug – must be diluted before administration to patient.

OVERDOSAGE: In case of accidental overdosage, as evidenced by excessive blood pressure elevation, reduce rate of administration or temporarily discontinue INTROPIN until patient's condition stabilizes. Since the drug's duration of action is quite short, no additional remedial measures are usually necessary. If these measures fail to stabilize the patient's condition, use of the short-acting alpha adrenergic blocking agent, phentolamine, should be considered.

HOW SUPPLIED:

– 200 mg (5 ml containing 40 mg dopamine HCl per ml). NDC 0094-0040-05 – Ampul. NDC 0094-0040-06 – Single-dose vial (color coded white). NDC 0094-0040-07 – RAP-ADD® Additive Syringe (color coded white).

– 400 mg (5 ml containing 80 mg dopamine HCl per ml). NDC 0094-0046-06 – Single-dose vial (color coded green). NDC 0094-0046-07 – RAP-ADD® Additive Syringe (color coded green).

CAUTION: Federal law prohibits dispensing without a prescription. Full directions for use should be read before administering or prescribing. November 1980

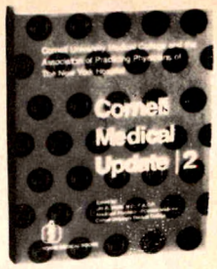
Now in book form...the latest
Update Your Medicine lectures.

CORNELL MEDICAL UPDATE/2



Edited by LILA A. WALLIS, MD, FACP

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

All new material—specialties expanded.

The workbook format of the CORNELL MEDICAL UPDATE/2 breaks medical publishing traditions by giving practicing physicians a quick overview of the latest advances in their specialty. It transcribes the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical Center. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice.

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 5th Ave., N.Y., N.Y. 10103 AJC 1/81

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00. I may use the book for 30 days and if not completely satisfied, return it for full refund or credit.

ATIONS AND CONTRAINDICATIONS

ndications for cardiac pacemaking are increasing as pace- become more sophisticated and as advanced methods for management become more widespread. Generally accepted ons for long-term cardiac pacing include but are not limited ck sinus syndrome; (2) chronic, symptomatic drug-resistant rhythmias, including sinus bradycardia, sinus arrest, and sinoatrial (S-A) block as seen in sick sinus syndrome; (3) chronic, symptomatic second-degree or third-degree A-V block; (4) recurrent Adams-Stokes syndrome; (5) bradycardia-tachycardia syndrome; (6) symptomatic bilateral bundle branch block; and (7) hypersensitive carotid sinus syndrome (carotid sinus syncope). In addition, certain patients presenting with intractable, recurrent, congestive heart failure; cerebral or renal insufficiency; or recurrent, drug-resistant tachyarrhythmias who have been shown to benefit from temporary cardiac pacing are considered candidates for permanent cardiac pacemaking.

The indications for permanent pacing in the presence of ac myocardial infarction have not yet been rigorously defined. F to be considered include the location of the myocardial infarc presence or absence of symptoms, ventricular rate, mechanism the arrhythmias, and response to therapy. In general, sympto drug-resistant bradyarrhythmias which impair cardiac output considered indications for pacing in patients with acute myoc infarction, regardless of infarct location.

A CyberLith® Pacemaker helped make these pictures of Wayne Sackett possible.

A LIFETIME OF MASSIVE HEART PROBLEMS IS BEING CONTROLLED WITH A CYBERLITH PACEMAKER, AN AORTIC VALVE, AND SELECTED DRUG THERAPY.

You'd never know by looking at him now, but ten years ago this man collapsed from disabling palpitations while mowing the lawn.

But thanks to an Intermedics CyberLith pacemaker, an aortic valve replacement, and continuing drug therapy, Wayne D. Sackett is more than just back on his feet. He's an active family man, a farmer, and Chief Plant Operator of the Water Department of Deland, Florida.

Taking care of an 11-acre farm is no small task, but Wayne and his wife enjoy making it a family affair with their three children. And the children know that when the chores are all done, it's time for play. Wayne has his favorites—softball, water skiing, fishing, and hunting—and the rest of the family likes to get in on the action.

For Wayne Sackett, as well as his family, the multi-programmable CyberLith pacemaker from Intermedics has proved to be more than a life-saver. In combination with the new valve and the drug therapy, it has been a life-enhancer. And because his physician has him telephonically monitored on a regular basis and can noninvasively make any changes necessary, chances are good that Wayne and his family can go on living as actively as they are now.

Wayne's CyberLith is just one model in the growing Intermedics family of thin, lightweight pacemakers that permit noninvasive programming of stimulating rate, pulse width, sensitivity level, and pacing mode. Because of the CyberLith's long history of reliability—longer than any other programmable multi-parameter pacemaker line—Wayne will probably still be going strong when his five-year-old son is in college.

CyberLith. It could be the pacemaker of choice for your patients.

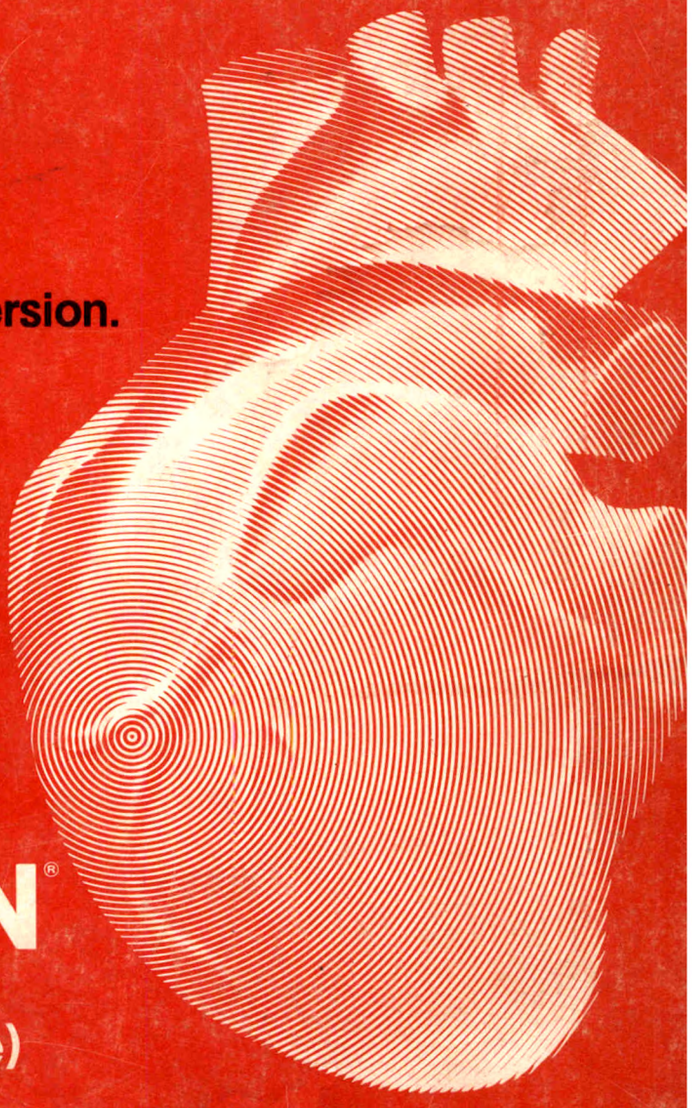
The Pacekeeper™

For ventricular arrhythmias.
For atrial arrhythmias.
For smooth, trouble-free conversion.
For steady maintenance.



CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

- ☐ Greater GI tolerance than with quinidine sulfate
- ☐ Full quinidine cardiodynamics
- ☐ Convenient b.i.d. or t.i.d. dosage for most patients

CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of a broad range of cardiac arrhythmias (see Brief Summary). After conversion to normal sinus rhythm —whether with CARDIOQUIN Tablets or electroconversion— only low b.i.d. or t.i.d. dosage of this unique polygalacturonate salt of quinidine is required for maintenance in most cases. The polygalacturonic acid serves as a buffering moiety. It protects the mucosa of the stomach and permits dependable absorption of the quinidine.*

*Aviado, D. M., Krantz and Carr's Pharmacologic Principles of Medical Practice, ed. 8, Baltimore, Williams and Wilkins Co., 1972, p. 456.

BRIEF SUMMARY—INDICATIONS: CARDIOQUIN Tablets (quinidine polygalacturonate) are indicated in the treatment of: premature atrial and ventricular contractions; paroxysmal atrial tachycardia; paroxysmal AV junctional rhythm; atrial flutter; paroxysmal atrial fibrillation; established atrial fibrillation when therapy is appropriate; paroxysmal ventricular tachycardia when not associated with complete heart block; maintenance therapy after electrical conversion of atrial fibrillation and/or flutter. CONTRAINDICATIONS: Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine. WARNING: In the treatment of atrial flutter reversion to sinus rhythm may be preceded by a progressive reduction in the degree of AV block to a 1:1 ratio and resulting extremely rapid ventricular rate. COMPOSITION: Each CARDIOQUIN Tablet (quinidine polygalacturonate 275 mg.) is equivalent in quinidine content to 3 grains quinidine sulfate. DOSAGE AND ADMINISTRATION: Dosage must be adjusted to individual needs, both for conversion and maintenance. An initial dose of 1 to 3 tablets may be used to terminate arrhythmias, and may be repeated in 3-4 hours. If normal sinus rhythm is not restored after 3 or 4 equal doses, the dose may be increased by ½ to 1 tablet (137.5 to 275 mg.) and administered three to four times before any further dosage increase. For maintenance, one tablet may be used two to three times a day; generally one tablet morning and night will be adequate. SUPPLIED: Uncoated, scored tablets in bottles of 100.

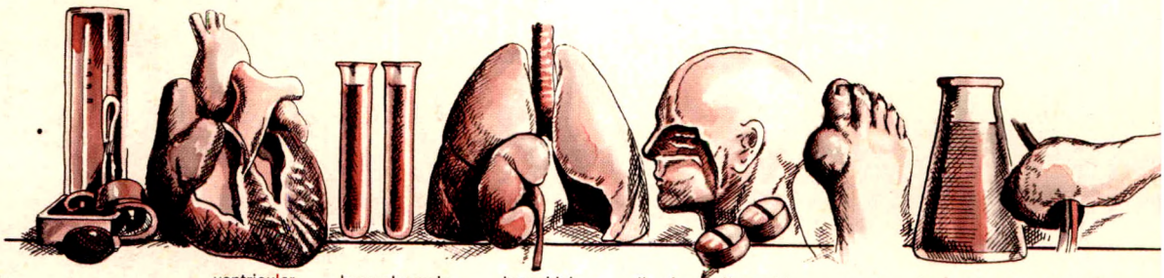
ANSWERS ABOUT ALDOMET® (METHYLDOPA|MSD)

Can an antihypertensive be used in older patients, even those who have certain concurrent diseases?

Special consideration should be given in the selection of an antihypertensive agent for the older patient—especially as to its suitability in the presence of other coexisting problems.

Highly effective and generally well tolerated, ALDOMET can be used in a wide range of hyp tensives, including many older patients with cer concurrent diseases. Its use therefore enhances t possibilities of successful long-term therapy in th older patient.



ALDOMET® offers many other important features:
(METHYLDOPA|MSD)

- Highly effective in all degrees of hypertension.
- Existing cardiac output is usually maintained.
- Renal blood flow is usually maintained.
- May be used in certain cases of complicated hypertension.
- Has documented long-term efficacy.
- Symptomatic postural hypotension is infrequent and the agent is usually well tolerated.

Syncope in older patients may be related to increased sensitivity and advanced arteriosclerotic vascular disease. This may be avoided by lower d ALDOMET is contraindicated in active hepatic disease, hypersensitivity to the drug, or if previou methyldopa therapy has been associated with liv disorders.

It is important to recognize that a positive Coc test, hemolytic anemia, and liver disorders may c with methyldopa therapy. The rare occurrences c hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed.

For hypertension—

ALDOMET (METHYLDOPA | MSD

The most prescribed nondiuretic antihypertensive in the U.S. today

Contraindications: Active hepatic disease such as acute hepatitis and active cirrhosis; if previous methyldopa therapy has been associated with liver disorders (see Warnings); hypersensitivity.

Warnings: It is important to recognize that a positive Coombs test, hemolytic anemia, and liver disorders may occur with methyldopa therapy. The rare occurrences of hemolytic anemia or liver disorders could lead to potentially fatal complications unless properly recognized and managed. Read this section carefully to understand these reactions.

With prolonged methyldopa therapy, 10% to 20% of patients develop a positive direct Coombs test, usually between 6 and 12 months of therapy. Lowest incidence is at daily dosage of 1 g or less. This on rare occasions may be associated with hemolytic anemia, which could lead to potentially fatal complications. One cannot predict which patients with a positive direct Coombs test may develop hemolytic anemia. Prior existence or development of a positive direct Coombs test is not in itself a contraindication to use of methyldopa. If a positive Coombs test develops during methyldopa therapy, determine whether hemolytic anemia exists and whether the positive Coombs test may be a problem. For example, in addition to a positive direct Coombs test there is less often a positive indirect Coombs test which may interfere with cross matching of blood.

At the start of methyldopa therapy, it is desirable to do a blood count (hematocrit, hemoglobin, or red cell count) for a baseline or to establish whether there is anemia. Periodic blood counts should be done during therapy to detect hemolytic anemia. It may be useful to do a direct Coombs test before therapy and at 6 and 12 months after the start of therapy. If Coombs-positive hemolytic anemia occurs, the cause may be methyldopa and the drug should be discontinued. Usually the anemia remits promptly. If not, corticosteroids may be given and other causes of anemia should be considered. If the hemolytic anemia is related to methyldopa, the drug should not be reinstituted. When methyldopa causes Coombs positivity alone or with hemolytic anemia, the red cell is usually coated with gamma globulin of the IgG (gamma G) class only. The positive Coombs test may not revert to normal until weeks to months after methyldopa is stopped.

Should the need for transfusion arise in a patient receiving methyldopa, both a direct and an indirect Coombs test should be performed on his blood. In the absence of hemolytic anemia, usually only the direct Coombs test will be positive. A positive direct Coombs test alone will not interfere with typing or cross matching. If the indirect Coombs test is also positive, problems may arise in the major cross match and the assistance of a hematologist or transfusion expert will be needed.

Fever has occurred within first 3 weeks of therapy, occasionally with eosinophilia or abnormalities in liver function tests, such as serum alkaline phosphatase, serum transaminases (SGOT, SGPT), bilirubin, cephalin cholesterol flocculation, prothrombin time, and bromsulphalein retention. Jaundice, with or without fever, may occur, with onset usually in the first 2 to 3 months of therapy. In some patients the findings are consistent with those of cholestasis. Rarely fatal hepatic necrosis has been reported. These hepatic changes may represent hypersensitivity reactions; periodic determination of hepatic function should be done particularly during the first 6 to 12 weeks of therapy or whenever an unexplained fever occurs. If fever and abnormalities in liver function tests or jaundice appear, stop therapy with methyldopa. If caused by methyldopa, the temperature and abnormalities in liver function characteristically have reverted to normal when the drug was discontinued. Methyldopa should not be reinstituted in such patients.

Rarely, a reversible reduction of the white blood cell count with primary effect on granulocytes has been seen. Reversible thrombocytopenia has occurred rarely. When used with other antihypertensive drugs, potentiation of antihypertensive effect may occur. Patients should be followed carefully to detect side reactions or unusual manifestations of drug idiosyncrasy.

Pregnancy and Nursing: Use of any drug in women who are or may become pregnant or intend to nurse requires that anticipated benefits be weighed against possible risks; possibility of fetal injury or injury to a nursing infant cannot be excluded. Methyldopa crosses the placental barrier, appears in cord blood, and appears in breast milk.

Precautions: Should be used with caution in patients with history of previous liver disease or dysfunction (see Warnings). May interfere with measurement of: urinary uric acid by the phosphotungstate method, serum creatinine by the alkaline picrate method, and SGOT by colorimetric methods. Since methyldopa causes fluorescence in urine samples at the same wavelengths as catecholamines, falsely high levels of urinary catecholamines may be reported. This will interfere with the diagnosis of pheochromocytoma. It is important to recognize this phenomenon before a patient with a possible pheochromocytoma is subjected to surgery. Methyldopa is not recommended for patients with pheochromocytoma. Urine exposed to air after voiding may darken because of breakdown of methyldopa or its metabolites.

Stop drug if involuntary choreoathetotic movements occur in patients with severe bilateral cerebrovascular disease. Patients may require reduced doses
anesthetics; hypotension occurring during ane
thesia usually can be controlled with vasopresso
Hypertension has recurred after dialysis in patier
on methyldopa because the drug is removed by tl
procedure.

Adverse Reactions: *Central nervous system:* Sec
tion, headache, asthenia or weakness, usually ea
and transient; dizziness, lightheadedness, sym
toms of cerebrovascular insufficiency, paresthesia
parkinsonism, Bell's palsy, decreased mental acui
involuntary choreoathetotic movements; psyct
disturbances, including nightmares and reversit
mild psychoses or depression.
Cardiovascular: Bradycardia, aggravation of angi
pectoris. Orthostatic hypotension (decrease da
dosage). Edema (and weight gain) usually relieved
use of a diuretic. (Discontinue methyldopa if eden
progresses or signs of heart failure appear.)
Gastrointestinal: Nausea, vomiting, distention, co
stipation, flatus, diarrhea, mild dryness of mout
sore or "black" tongue, pancreatitis, sialadenitis.
Hepatic: Abnormal liver function tests, jaundic
liver disorders.
Hematologic: Positive Coombs test, hemolytic an
mia. Leukopenia, granulocytopenia, thrombocyt
penia. Positive tests for antinuclear antibody, L
cells, and rheumatoid factor.
Allergic: Drug-related fever, lupus-like syndrom
myocarditis.
Other: Nasal stuffiness, rise in BUN, breast enlarg
ment, gynecomastia, lactation, impotence, d
creased libido, dermatologic reactions includin
eczema and lichenoid eruptions, mild arthralgi
myalgia.

Note: Initial adult dosage should be limited t
500 mg daily when given with antihypertensive
other than thiazides. Tolerance may occur, usuall
between second and third months of therap
increased dosage or adding a diuretic frequentl
restores effective control. Patients with impaire
renal function may respond to smaller doses
Syncope in older patients may be related to increase
sensitivity and advanced arteriosclerotic vascula
disease; this may be avoided by lower doses.

How Supplied: Tablets, containing 125 mg methyl
dopa each, in bottles of 100; Tablets, containin
250 mg methyldopa each, in single-unit packages c
100 and bottles of 100 and 1000; Tablets, containin
500 mg methyldopa each, in single-unit packages c
100 and bottles of 100 and 500.

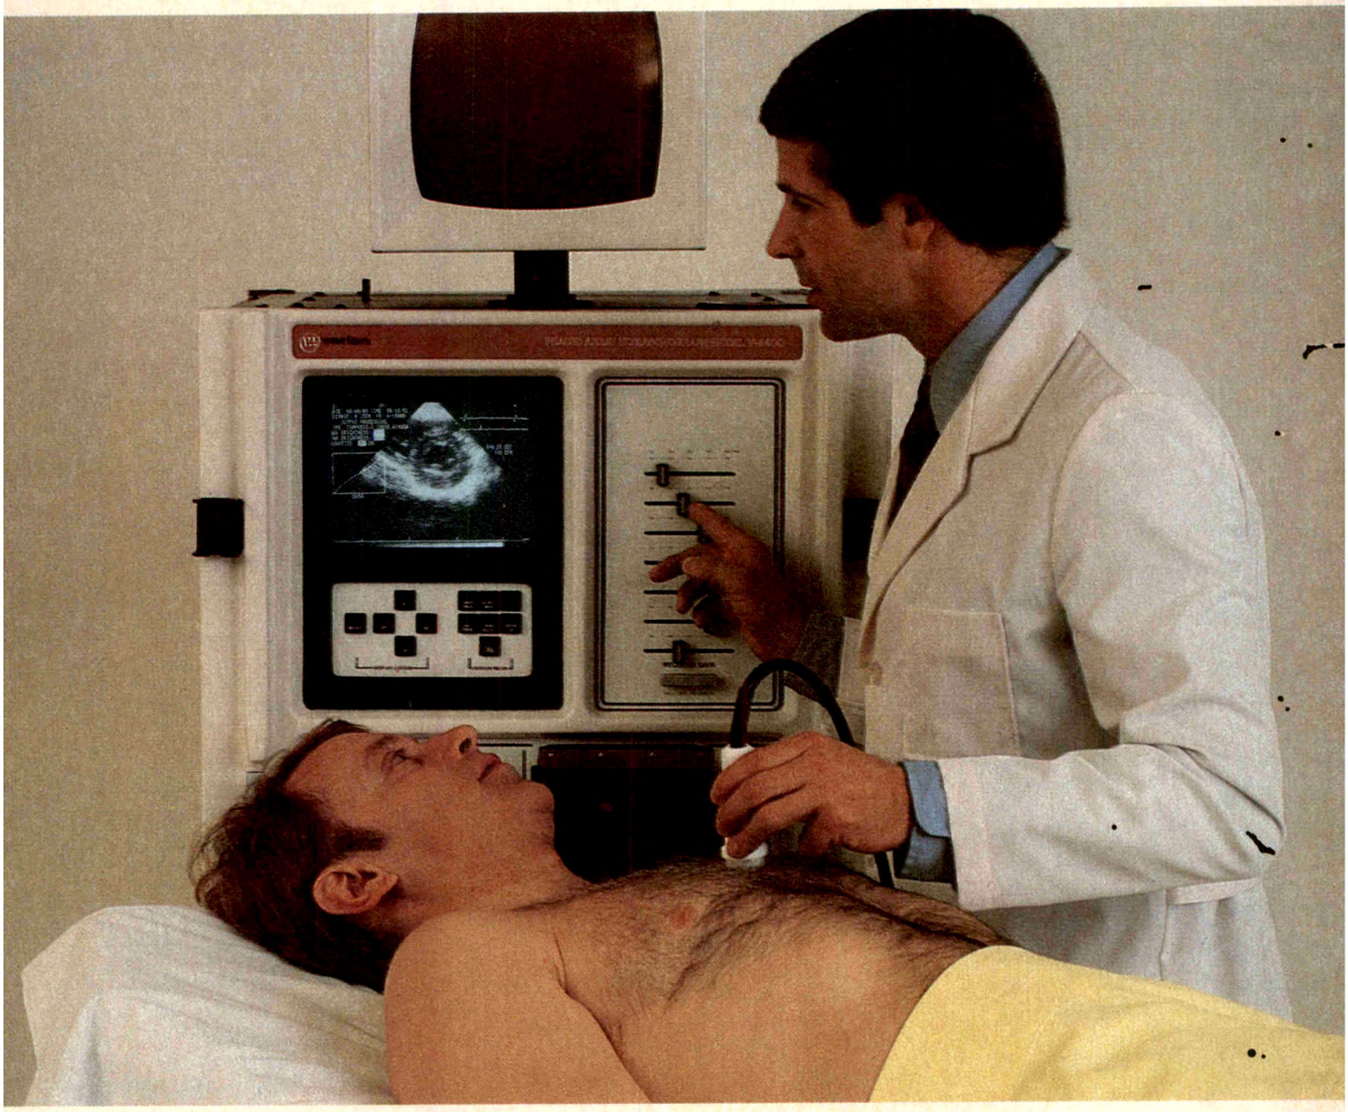
VARIAN V-3400

Setting New Standards In Sector Scanning



FEATURES

Digital Scan Processor (DSP)

The Varian DSP uses a powerful microprocessor system to fully utilize digital technology for processing the ultrasound image.

Phased Array Design

Varian pioneered the success of phased array transducer technology, which requires no moving parts and yields significant performance advantages.

Varian Ultrasound

From pioneer to premier manufacturer, Varian is a major high-technology corporation consistently leading the way in product technology, responsive field service, and customer education.

BENEFITS

Excellent Imaging Quality

The V-3400 produces clear, low noise, high sensitivity, diagnostic quality images from all major anatomic windows.

Dependable Performance

Inherent reliability, solid state electronics, and phased array design combine with Varian's experience and extensive customer support to assure dependable clinical performance.

Advanced Clinical Capability

Fast, accurate examinations, recording, and quantitation are enhanced by the V-3400's advanced clinical features such as variable persistence, pre and post processing, simultaneous M-mode, and the light pen measurement system.

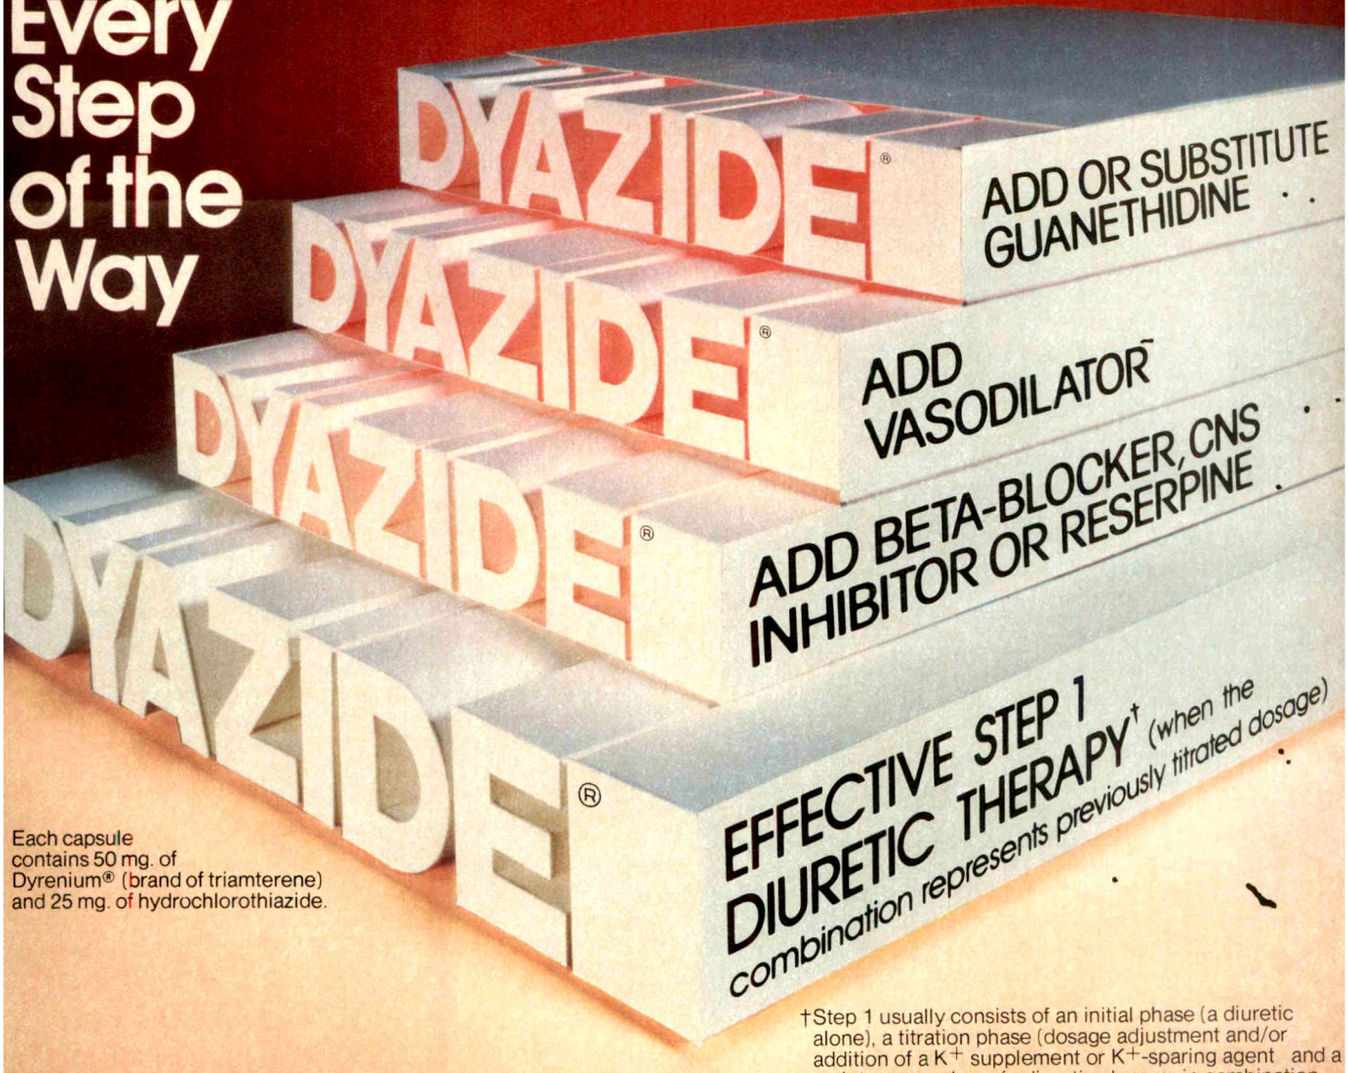
In Hypertension*...When You Need to Conserve K^+

Every Step of the Way



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

†Step 1 usually consists of an initial phase (a diuretic alone), a titration phase (dosage adjustment and/or addition of a K^+ supplement or K^+-sparing agent and a maintenance phase (a diuretic alone or in combination with a K^+ supplement or K^+-sparing agent).

Serum K^+ and BUN should be checked periodically (see Warnings).

Before prescribing, see complete prescribing information in SK&F Co. literature or *PDR*. A brief summary follows:

WARNING
This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Watch for signs of impending coma in severe liver disease. If spironolactone is used concomitantly, determine serum K^+ frequently; both can cause K^+ retention and elevated serum K^+. Two deaths have been reported with such concomitant therapy (in one, recommended dosage was exceeded, in the other serum electrolytes were not properly monitored). Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic anemia have been reported with thiazides. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effect may be enhanced in postsympathectomy patients. Use cautiously in surgical patients. The following may occur: transient elevated BUN or creatinine or both, hyperglycemia and glycosuria (diabetic insulin requirements may be altered), hyperuricemia and gout, digitalis intoxication (in hypokalemia), decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia, although uncommon, has been reported. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth; anaphylaxis; rash, urticaria, photosensitivity, purpura, other dermatological conditions; nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances. Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and, rarely, allergic pneumonitis have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components.

Supplied: Bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

new 50 mg tablets...

Persantine®-50

(dipyridamole)

21% savings (over 25 mg)

NEW dosage convenience— one tablet instead of two

NEW prescribing flexibility— Persantine now available in three strengths...25 mg, 50 mg and 75 mg

Persantine® (dipyridamole)

INDICATIONS—Based on a review of this drug by the National Academy of Sciences National Research Council and/or other information, FDA has classified the indication as follows:

"Possibly" effective: For long-term therapy of chronic angina pectoris. Prolonged therapy may reduce the frequency or eliminate anginal episodes, improve exercise tolerance, and reduce nitroglycerin requirements. The drug is not intended to abort the acute anginal attack.

Final classification of the less-than-effective indications requires further investigation.

CONTRAINDICATIONS—No specific contraindications are known.

PRECAUTIONS—Since excessive doses can produce peripheral vasodilation, the drug should be used cautiously in patients with hypotension. Persantine tablets, 25 mg, contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. The incidence of sensitivity is generally low, but frequently seen in patients with aspirin hypersensitivity.

ADVERSE REACTIONS—Adverse reactions are minimal and transient at recommended dosages. Instances of headache, dizziness, nausea, flushing, weakness or syncope, mild gastrointestinal distress and skin rash have been noted during therapy. Rare cases of what appeared to be an aggravation of angina pectoris have been reported, usually at the initiation of therapy. On those uncommon occasions when adverse reactions have been persistent or intolerable, withdrawal of medication has been followed promptly by cessation of undesirable symptoms.

DOSAGE AND ADMINISTRATION—The recommended dosage is 50 mg three times a day, taken at least one hour before meals. In some cases, higher doses may be necessary but a significantly increased incidence of side effects is associated with increased dosage. Clinical response may not be evident before the second or third month of continuous therapy.

Tablets of 25 mg, 50 mg and 75 mg

For patients who need K^+Cl^- one sparkles bright:

KLORVESS® EFFERVESCENT GRANULES offer SPARKLING FAST DISSOLUTION

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

- **ready in *seconds* instead of minutes —fast dissolution so unique it's patented***
- **pleasant citrus flavor**
- **each packet delivers 20 mEq of potassium and chloride**
- **easily carried in patient's pocket or purse**
- **can be mixed with water or other liquid for pleasant daily dosage**
- **sugar, sodium, carbohydrate and dye free**

Give your patients the KLORVESS sparkle

Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

New evidence is in:

Treatment of mild hypertension can save lives

Even among patients with DBP in the low 90. systematic therapy significantly reduced mortality:

- Of nearly 11,000 hypertensives identified by the Hypertensic Detection and Follow-up Program, slightly more than 70% ha mild hypertension (DBP 90-104 mm. Hg).[1]
- Half were given systematic and aggressive care in HDFP cer ters; half were referred to customary sources of medical care.
- After 5 years, HDFP found that effective treatment of mild hypertension may reduce premature deaths by 20%.[1]
- As part of HDFP's systematic treatment and follow-up program, the primary step-1 agent was chlorthalidone: Hygroton®

The primary agent used by the HDFP in an effective low dose

Hygroton® 25 mg. one a day
(chlorthalidone USP)

Because there's nothing mild about mild hypertension

BRIEF SUMMARY

Indications: Hypertension, adjunctive therapy in edema. **Contraindications:** Anuria, hypersensitivity to chlorthalidone or other sulfonamide-derived drugs. **Warnings:** Should be used with caution in severe renal disease, impaired hepatic function or progressive liver disease. May add to or potentiate the action of other antihypertensive drugs. Sensitivity reactions may occur in patients with a history of allergy or bronchial asthma. There is a possibility of exacerbation or activation of systemic lupus erythematosus with thiazides, which are related to chlorthalidone. This has not been reported with chlorthalidone. Thiazides cross the placental barrier and appear in cord blood. Use in pregnant women requires that the anticipated benefits of the drug be weighed against possible hazards to the fetus. These hazards include fetal or neonatal jaundice, thrombocytopenia, and possibly other adverse reactions which have occurred in the adult. In nursing mothers, thiazides cross the placental barrier and appear in breast milk. If use of the drug is essential, the patient should stop nursing. **Precautions:** Periodic determination of serum electrolytes to detect possible electrolyte imbalance should be performed at appropriate intervals. All patients receiving chlorthalidone should be observed for clinical signs of fluid or electrolyte imbalance; namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with chlorthalidone as with any other potent diuretic, especially with brisk diuresis, when severe cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis therapy may exaggerate metabolic effects of hypokalemia especially with reference to myocardial activity. Any chloride deficit is generally mild and usually does not require specific treatment except under extraordinary circumstances (as in liver disease or renal disease). Dilutional hyponatremia may occur in edematous patients in hot weather. Hyperuricemia may occur or gout be precipitated in certain patients. Insulin requirements in diabetic patients may be increased, decreased, or unchanged and latent diabetes mellitus may become manifest. Chlorthalidone and related drugs may increase the responsiveness to tubocurarine. The antihypertensive effects of the drug may be enhanced in the postsympathectomy patient. Chlorthalidone and related drugs may decrease arterial responsiveness to norepinephrine. If progressive renal impairment becomes evident, as indicated by a rising nonprotein nitrogen or blood urea nitrogen, a careful reappraisal of therapy is necessary with consideration given to withholding or discontinuing diuretic therapy. Chlorthalidone and related drugs may decrease serum PBI levels without signs of thyroid disturbance. **Adverse Reactions:** Anorexia, gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic cholestatic jaundice), pancreatitis; dizziness, vertigo, paresthesias, headache, xanthopsia; leukopenia, agranulocytosis, thrombocytopenia, aplastic anemia; purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis) (cutaneous vasculitis), Lyell's syndrome (toxic epidermal necrolysis). Orthostatic hypotension may occur and may be aggravated by alcohol, barbiturates or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, impotence. Whenever adverse reactions are moderate or severe, chlorthalidone dosage should be reduced or therapy withdrawn. **Usual Dose:** One tablet daily. **How Supplied:** Tablets—100 mg. (white, scored), 50 mg. (aqua) in bottles of 100, 1000 and 5000; 25 mg. (peach) in bottles of 100 and 1000; unit-dose blister packs, boxes of 100 (10 x 10 strips).

FEBRUARY 1981 VOLUME 47 NUMBER 2 (IN TWO PARTS)

CONTENTS

CLINICAL STUDIES

193 Left Ventricular Function in Chronic Aortic Regurgitation With Reference to End-Systolic Pressure, Volume and Stress Relations

MARY OSBAKKEN, ALFRED A. BOVE and JAMES F. SPANN

This study of left ventricular contractile and pump function in 12 normal subjects and 21 patients with chronic aortic regurgitation, using conventional methods and the new measure of contractility developed by Sagawa, found the combination of decreased muscle function and increased demands on pump function causes a significant increase in end-diastolic pressure only in patients with heart failure. The contractile and pump functions are reduced when the chronic volume overload progresses to congestive heart failure, but contractile function appears normal and pump function is not significantly reduced in patients whose chronic volume overload has not yet progressed to congestive heart failure. These data also indicate that hypertrophy alone does not decrease myocardial performance. A degree of volume overload and of hypertrophy is associated with normal function, but severe overload with further hypertrophy results in decreased myocardial performance and clinical evidence of congestive heart failure. The data further suggest that patients with aortic regurgitation progress to a symptomatic state when the regurgitant volume becomes greater and the end-diastolic volume and pressure increase.

199 Coronary Sinus Blood Flow at Rest and During Isometric Exercise in Patients With Aortic Valve Disease. Mechanism of Angina Pectoris in Presence of Normal Coronary Arteries

MICHEL E. BERTRAND, JEAN M. LABLANCHE, PIERRE Y. TILMANT, FRANÇOIS P. THIEULEUX, MARC R. DELFORGE and ALAIN G. CARRÉ

These studies in 46 patients with aortic valve disease indicate that coronary blood flow and myocardial uptake of oxygen remain within normal limits in this disorder. Underperfusion of the subendocardial muscle, rather than failure of coronary sinus blood flow to increase, seemed to be a major causative factor in the 18 patients with angina on effort. Special care is needed to protect the myocardium and the subendocardium of these patients during surgical valve replacement. This reserve capacity of vasodilation is unimpaired in these patients as is the ability of the heart to adjust its coronary flow by autoregulation in response to exercise.

206 Congenitally Bicuspid Aortic Valve Causing Severe, Pure Aortic Regurgitation Without Superimposed Infective Endocarditis. Analysis of 13 Patients Requiring Aortic Valve Replacement

WILLIAM C. ROBERTS, ANDREW G. MORROW, CHARLES L. McINTOSH, MICHAEL JONES and STEPHEN E. EPSTEIN

Although not generally recognized as an important factor, the noninfected congenitally bicuspid aortic valve was an important cause of isolated pure aortic regurgitation severe enough to warrant aortic valve replacement in 13 of 189 patients aged 18 to 70 years who had such surgery at the National Heart, Lung, and Blood Institute. In contrast to these 13 patients, only 7 of the 189 patients had pure aortic regurgitation because of infective endocarditis involving a congenitally bicuspid aortic valve.

210 Delayed Pericardial Disease After Radiotherapy

MARK M. APPLEFELD, ROBERT G. SLAWSON, MARY HALL-CRAIGS, DAVID C. GREEN, ROBERT T. SINGLETON and PETER H. WIERNIK

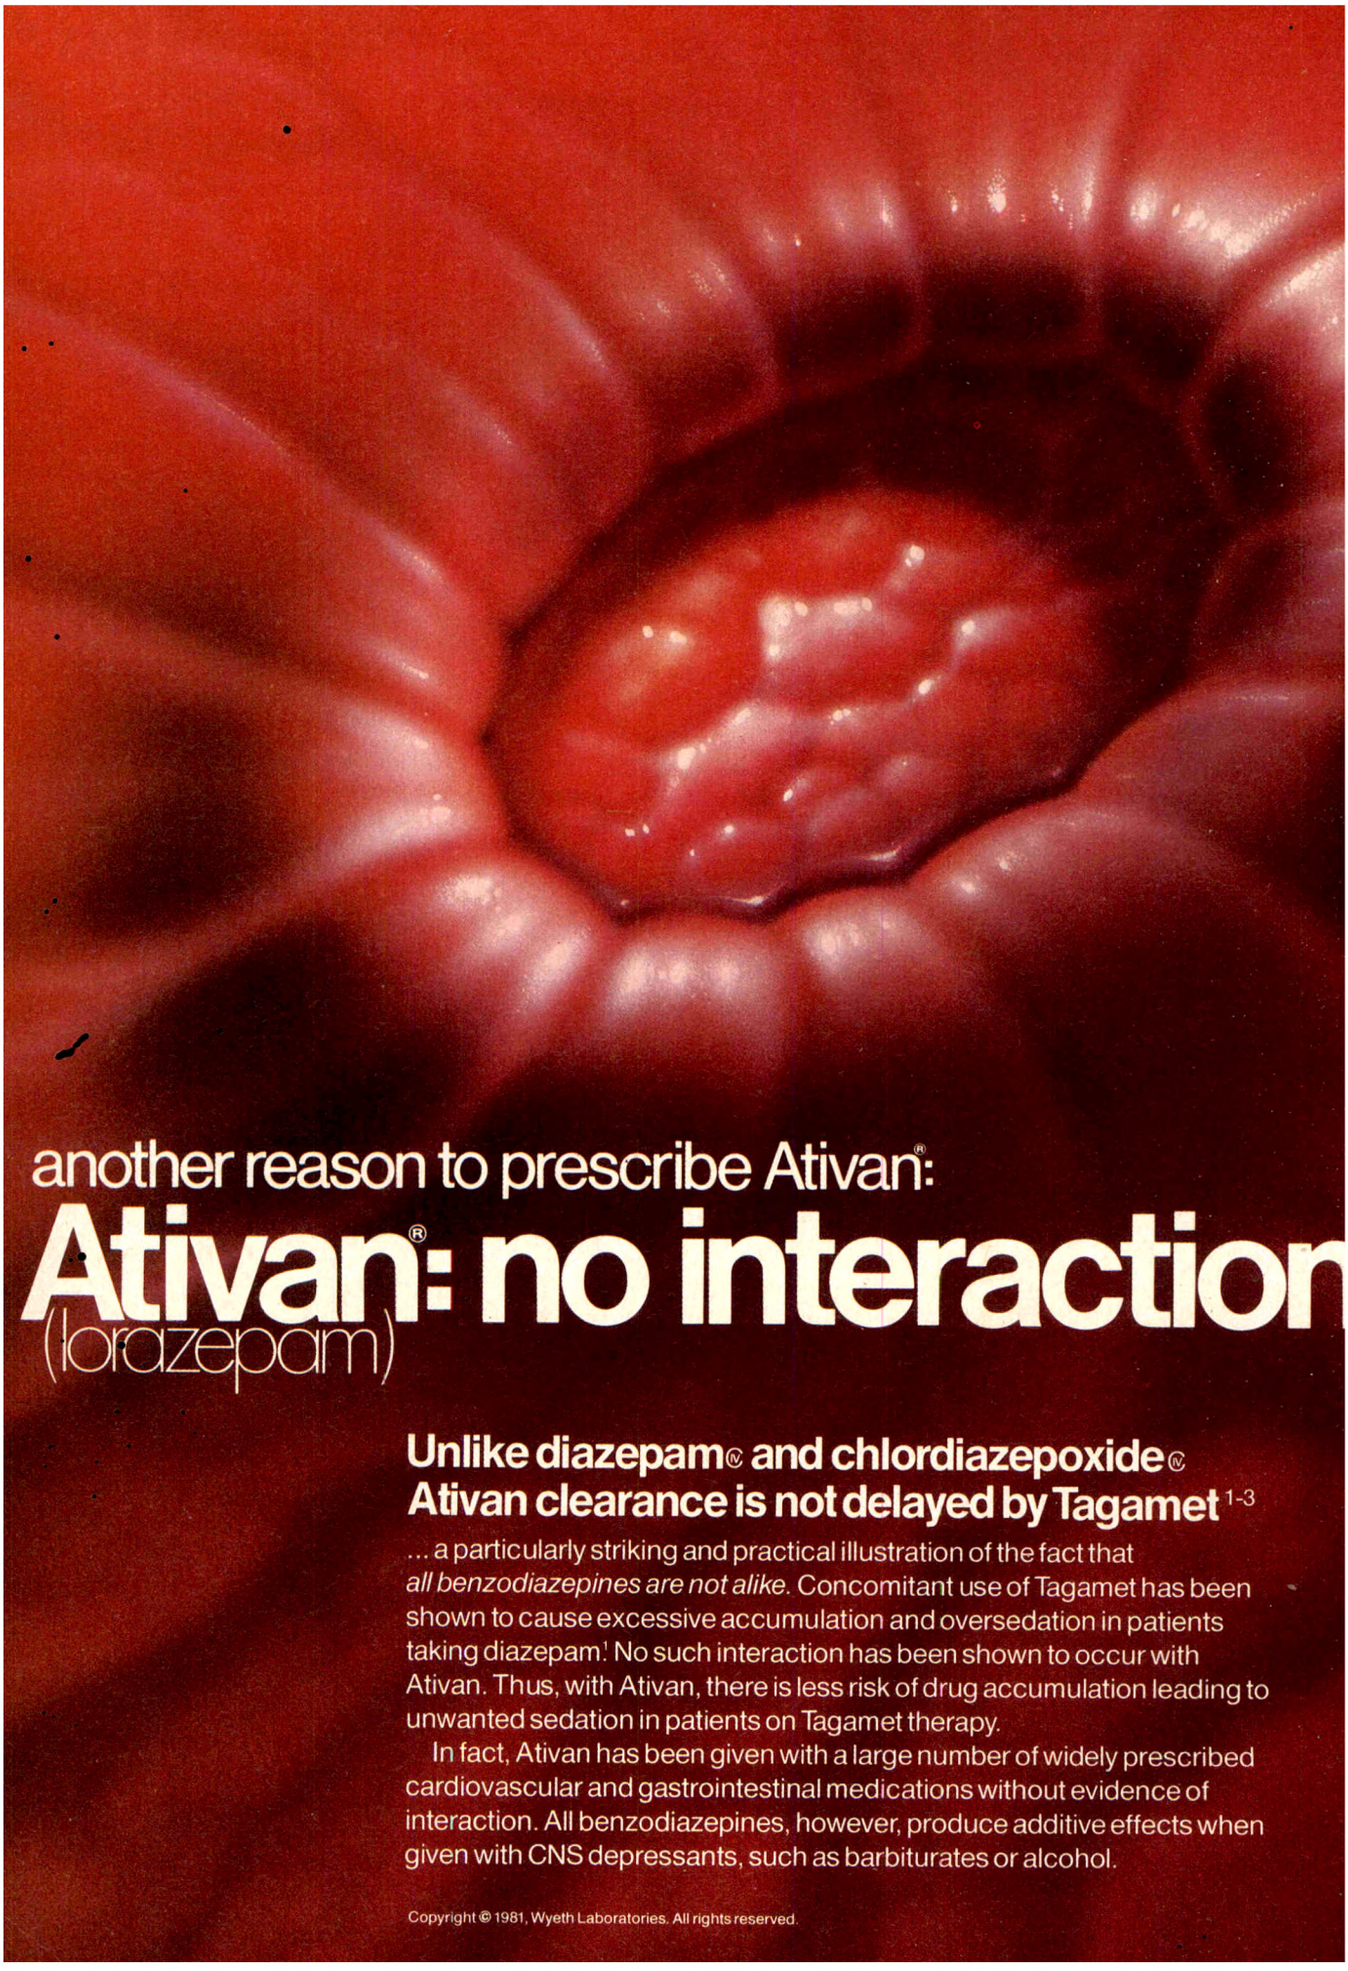
Delayed chronic constrictive pericarditis developed in seven patients 51 to 268 months after they were treated with radiotherapy to the chest for Hodgkin's disease (six patients) and a breast cancer (one patient). Several different pathophysiologic mechanisms may be responsible for such radiation-induced pericardial disease. A surgically produced subxiphoid pericardial window is recommended for patients with cardiac tamponade manifested by dyspnea, hypotension and an echocardiographically confirmed pericardial effusion. Pericardiectomy is recommended if cardiac catheterization confirms constrictive pericarditis in patients with incapacitating dyspnea or marked hepatomegaly (liver more than 16 cm in span). Surgery is not advised solely on the basis of hemodynamic confirmation of constrictive pericarditis or for the presence of recurrent pleural effusions.

214 Hypertrophic Obstructive Cardiomyopathy and Lentiginosis: A Little Known Neural Ectodermal Syndrome

MARTIN G. ST. JOHN SUTTON, ABDUL J. TAJIK, EMILIO R. GIULIANI, HYMIE GORDON and W. P. DANIEL Su

These 11 patients with classic hypertrophic obstructive cardiomyopathy and lentiginosis (a disorder of skin pigmentation that is of neural crest origin) lead these investigators to propose that cardiomyopathic lentiginosis and leopard syndrome are the same entity and that the cardiac lesion common to both is hypertrophic obstructive cardiomyopathy. The presence of lentiginosis, electrocardiographic abnormalities and a systolic murmur should

continued on page A16



another reason to prescribe Ativan®:

Ativan®: no interaction

(lorazepam)

Unlike diazepam℠ and chlordiazepoxide℠ Ativan clearance is not delayed by Tagamet[1-3]

... a particularly striking and practical illustration of the fact that *all benzodiazepines are not alike.* Concomitant use of Tagamet has been shown to cause excessive accumulation and oversedation in patients taking diazepam! No such interaction has been shown to occur with Ativan. Thus, with Ativan, there is less risk of drug accumulation leading to unwanted sedation in patients on Tagamet therapy.

In fact, Ativan has been given with a large number of widely prescribed cardiovascular and gastrointestinal medications without evidence of interaction. All benzodiazepines, however, produce additive effects when given with CNS depressants, such as barbiturates or alcohol.

Copyright © 1981, Wyeth Laboratories. All rights reserved.

with Tagamet®*

Other advantages of Ativan (lorazepam):

- Shorter half-life helps avoid excessive accumulation
- No active metabolites, less work for the liver
- B.I.D. dosage encourages compliance

†Anxiety or tension associated with the stress of everyday life usually does not require treatment with an anxiolytic.

See important information on following page.

Ativan® (lorazepam) ℞ for Anxiety

Wyeth Laboratories
Philadelphia, PA 19101

Brief Summary of Prescribing Information.

Indications and Usage: Management of anxiety disorders or short-term relief of symptoms of anxiety or anxiety associated with depressive symptoms. Anxiety or tension associated with stress of everyday life usually does not require treatment with an anxiolytic.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation. Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions. Observe usual precautions with impaired renal or hepatic function. Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component. Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (about 6 times maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatrics requires caution and frequent monitoring for symptoms of upper G.I. disease. Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug. In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for Anxiety
(lorazepam)

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Wyeth Laboratories
Philadelphia, PA 19101

Copyright © 1981 Wyeth Laboratories. All rights reserved.

Nitrol®
(nitroglycerin ointment, 2%)

Description: Nitrol® Ointment contains 2% nitroglycerin (glyceryl trinitrate) in a special lanolin-petrolatum base. It is a prompt acting vasodilator, effective in the relief and prevention of anginal attacks.

Action: When the ointment is spread on the skin, the active ingredient (nitroglycerin) is continuously absorbed through the skin into the circulation, thus exerting prolonged vasodilator effect. Nitroglycerin ointment is effective in the control of angina pectoris, regardless of the site of application.

Indications: Prevention and treatment of angina pectoris attacks.

Contraindications: May be contraindicated in patients with marked anemia, increased intraocular pressure or increased intracranial pressure. Should not be employed in patients with known idiosyncrasies to nitrites.

Warning: In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

Precautions: A hypotensive headache is a sign of overdosage. Occasionally elderly patients may have no untoward symptoms while recumbent but may develop postural hypotension with faintness upon suddenly arising.

Dosage and Administration: For angina pectoris the ointment may be applied every 3 to 4 hours as required. The usual dose is 1 to 2 inches, as squeezed from the tube, although some patients may require as much as 4 or 5 inches. The ointment should be spread in a thin uniform layer on the skin. The optimum dosage is determined by starting with an application of ½ inch of ointment and increasing the dose in ½ inch increments each successive application until headache occurs, then decreasing to the largest dose which does not cause headache. Nitrol Ointment can be applied to any convenient skin area but psychologically, many patients prefer the chest.

Measurement and application of the ointment is easily accomplished with the aid of the specially designed Appli-Ruler™ supplied with the ointment. The ointment can be squeezed onto the graduated area of the Appli-Ruler and conveniently spread over the desired skin area. Keep the tube tightly closed and store at controlled room temperatures.

Caution: Federal law prohibits dispensing without prescription.

Supplied:
30 gram tube NDC 0091-5617-31
60 gram tube NDC 0091-5617-02
30 gram 6-Pack Unit NDC 0091-5617-61
60 gram 6-Pack Unit NDC 0091-5617-62

Nitrol® (nitroglycerin ointment, 2%)
Fills a therapeutic void in your cardiology practice

Nitrol Ointment—the original topical coronary vasodilator—provides subjective symptomatic improvement for your angina patients; long-lasting freedom from pain and discomfort; possible reduction in oral medication requirements; decreased nocturnal attacks; overall symptomatic improvement.

The clinical efficacy of Nitrol has been confirmed in 12 published studies.

- supplements sublingual nitroglycerin medication
- provides consistently prolonged beneficial hemodynamic effects[1,4]
- produces sustained, enhanced exercise capacity; concomitant changes in heart rate and blood pressure—without evidence of tolerance or toxicity[1]
- decreases pulmonary wedge and arterial pressures plus systemic diastolic arterial pressures up to 5 hours[2]
- favorably affects peripheral vascular resistance, venous capacitance, preload and afterload[3,4]

For additional Nitrol information contact:

Kremers-Urban Company

(See preceding page for full prescribing information.)

CONTENTS

raise the clinical suspicion of coexistent hypertrophic obstructive cardiomyopathy. Ten o severely symptomatic and 7, each with a left ventricular pressure gradient of more than successful septal myotomy/myectomy with long-term marked symptomatic improvement

218 **History and Physical Examination in Acute Pulmonary Embolism in Patients Without Cardiac or Pulmonary Disease**

PAUL D. STEIN, PARK W. WILLIS III and DAVID L. DeMETS

In this group of 215 patients with acute pulmonary embolism uncomplicated by preexisting disease, dyspnea (84 percent) was the most frequent symptom and tachypnea (85 perce quent sign. Deep venous thrombosis was identified in 41 percent. Dyspnea, tachypnea or c sis was present in 99 percent of patients. Acute pulmonary embolism was rarely identified specific changes of the S-T segment or T wave in the electrocardiogram were found in m the patients with massive or submassive acute pulmonary embolism. A normal electroca mon. The most common abnormalities in the plain chest roentgenogram were pleural Greater reliance on the clinical manifestations will improve the selection of patients for pu and may decrease the reported high frequency of negative pulmonary arteriograms.

224 **Bedside Recognition, Incidence and Clinical Course of Right Ventricular Infarction**

GUILLERMO B. CINTRON, EDGARDO HERNANDEZ, ESTEBAN LINARES and JUAN M

Sixteen of 44 patients with acute inferior wall myocardial infarction had evidence of right Their clinical course was not different from that of others without signs of right ventricu bedside physical diagnosis demonstrating a positive Kussmaul's sign and a right ventricul sound can identify these patients. Right ventricular infarction clinically presents a wide s a rather benign uncomplicated entity to a catastrophic event with atrioventricular block, s Appropriate therapy, including expansion of intravascular volume and use of inotropic ag acute right ventricular infarction and systemic hypoperfusion secondary to inadequate pressure usually produces a satisfactory result.

228 **Unstable Angina Pectoris of New Onset: A Prospective Clinical and Arteriographic S Patients**

MARK F. VICTOR, MARIELL J. LIKOFF, GARY S. MINTZ and WILLIAM LIKOFF

Arteriographic data in 75 patients with unstable angina pectoris of new onset showed ar dence (52 percent) of single vessel coronary artery disease predominantly involving the le coronary arteries, suggesting that these patients constitute a unique subset of patients with patients with single vessel disease did not differ from those with multivessel involvemer factors or clinical presentation. Of the 75 studied, 60 had significant coronary artery dise insignificant coronary disease or entirely normal coronary arteries. Analysis of the 60 pa coronary disease revealed that 52 percent had single, 18 percent had double and 15 per disease and 15 percent had disease of the left main coronary artery either alone or in asso sels.

233 **Prognostic Importance of Anginal Symptoms in Angiographically Defined Coronary A**

PETER F. COHN, PHILLIP HARRIS, WILLIAM H. BARRY, ROBERT A. ROSATI, PAUL CHRISTINE WATERNAUX

Comparison of 44 patients with angiographically defined coronary artery disease and no time of cardiac catheterization with 127 symptomatic patients with similar coronary ana function showed an annual mortality rate of 2.7 percent in the asymptomatic group and 5. with angina. The results of this study suggest that the presence of angina is an important prognosis, but the reasons remain conjectural because the absence of angina neither prec ease nor implies a benign prognosis. The subgroup of asymptomatic patients with three yearly mortality rate of nearly 5 percent. The value of prophylactic medical or surgical treat is unclear at present.

238 **Analysis of Exercise-Induced Changes in R Wave Amplitude in Asymptomatic Men V Electrocardiographic ST-T Changes at Rest**

JOHN YIANNIKAS, JIANIS MARCOMICHELAKIS, PETER TAGGART, BRIAN H. KELLY RICHARD EMANUEL

Symptom-limited treadmill exercise testing of 50 asymptomatic male pilots or allied aviato ing ST-T electrocardiographic changes indistinguishable from those of myocardial ischemi cidence rate of positive results when S-T segment criteria were used. Analysis of changes yielded only two false positive results in men with other heart diseases. Diminished R wave cise, even in the presence of a positive test based on S-T segment criteria, strongly sug coronary artery disease, making coronary angiography unnecessary.

Pronestyl®

(Procainamide Hydrochloride)

Please see next page for brief summaries.

PRONESTYL® INJECTION
Procainamide Hydrochloride Injection USP

DESCRIPTION: Pronestyl Injection (Procainamide Hydrochloride Injection USP) is a sterile, aqueous solution providing 100 mg or 500 mg procainamide hydrochloride per ml. The 100 mg/ml potency contains 0.9% (w/v) benzyl alcohol and 0.09% sodium bisulfite as preservatives. The 500 mg/ml potency contains 0.1% methylparaben and not more than 0.2% sodium bisulfite as preservatives.

CONTRAINDICATIONS: In patients with myasthenia gravis and where a hypersensitivity to procainamide exists; cross sensitivity to procaine and related drugs must be borne in mind. Should not be given to patients with complete atrioventricular heart block. Contraindicated in cases of high-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: Evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of myocardial damage, procainamide may produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed; adequate digitalization reduces but does not abolish this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. The dislodgment of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of the atrium.

Extreme caution is required in attempting to adjust the heart rate when ventricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation as in A-V block, bundle branch block, or severe digitalis intoxication.

Parenteral administration should be monitored electrocardiographically whenever practicable. Parenteral administration should be discontinued at once if electrocardiograms give evidence of impending heart block. This complication should be kept in mind when treating ventricular arrhythmias (especially parenterally) in patients with severe organic heart disease and ventricular tachycardia who may also have complete heart block. Since asystole may result if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the patient re-evaluated.

In the presence of both liver and kidney damage, normal dosage may produce symptoms of overdosage — principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with oral maintenance procainamide therapy. Common symptoms are polyarthralgia, arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion and pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patients on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; discontinue drug in event of rising titer or clinical symptoms of LE. Steroid therapy may be effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

ADVERSE REACTIONS: Because procainamide is a peripheral vasodilator, I.V. administration may produce transient but at times severe hypotension particularly in conscious patients. I.M. injection is less likely to cause serious falls in blood pressure. Serious disturbances of cardiac rhythm such as ventricular asystole or fibrillation are also more common with I.V. administration.

A syndrome resembling lupus erythematosus has been reported in patients on oral maintenance therapy. Reactions consisting of fever and chills including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in SGOT following single doses of the drug have been reported. Bitter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, hypersensitivity reactions such as angioneurotic edema and maculopapular rash have been reported. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred; therefore, routine blood counts are advisable during maintenance therapy. If soreness of mouth, throat or gums, unexplained fever or any symptoms of upper respiratory tract infection should occur and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

For full prescribing information, consult package insert.

HOW SUPPLIED: Pronestyl Injection (Procainamide Hydrochloride Injection USP) is available in 10 ml vials providing 100 mg procainamide hydrochloride per ml and in 2 ml vials providing 500 mg procainamide hydrochloride per ml.

PRONESTYL® TABLETS
Procainamide Hydrochloride Tablets
PRONESTYL® CAPSULES
Procainamide Hydrochloride Capsules USP

The prolonged administration of procainamide often leads to the development of a positive anti-nuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

DESCRIPTION: Pronestyl (Procainamide Hydrochloride) is the amide analogue of procaine hydrochloride and is available for oral administratio capsules and veneer-coated tablets providing 250 mg, 375 mg, and 500 mg procainamide hydrochloride. Pronestyl Tablets contain FD&C Yellow No. (tartrazine).

CONTRAINDICATIONS: In patients with myasthenia gravis and where hypersensitivity to procainamide exists; bear in mind cross sensitivity to pr caine and related drugs. Should not be given to patients with complete atr ventricular heart block. Contraindicated in cases of second degree and thi degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: Evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of myocardial damag with atrial fibrillation or flutter, the ventricular rate may increase suddenl the atrial rate is slowed; adequate digitalization reduces but does not aboli this danger. Ventricular tachysystole is particularly hazardous if myocardi damage exists.

The dislodgment of mural thrombi producing an embolic episode may occur in correcting atrial fibrillation due to the forceful contractions of th atrium.

Extreme caution is required in attempting to adjust the heart rate when tricular tachycardia has occurred during an occlusive coronary episode or where the use of procainamide may result in additional depression of cond tion and ventricular asystole or fibrillation as in second degree and third degree A-V block, bundle branch block, or severe digitalis intoxication.

Bear in mind when treating ventricular arrhythmias in patients with seve organic heart disease and ventricular tachycardia that complete heart bloc which may be difficult to diagnose, may be present. Since asystole may res if the ventricular rate is significantly slowed without attainment of regular atrioventricular conduction, procainamide should be stopped and the pati reevaluated.

In the presence of both liver and kidney damage, normal dosage may pr duce symptoms of overdosage — principally ventricular tachycardia and severe hypotension.

A syndrome resembling lupus erythematosus has been reported with ora maintenance procainamide therapy. Common symptoms are polyarthralgi arthritis and pleuritic pain. Fever, myalgia, skin lesions, pleural effusion a pericarditis may also occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia, possibly related to this syndrome, have been reported. Measure anti-nuclear antibody titers at regular intervals in patie on procainamide for extended periods of time or in whom symptoms suggestive of lupus-like reaction appear; in event of rising titer (anti-nuclear antibody) or clinical symptoms of LE, assess the benefit/risk ratio related continued procainamide therapy (see boxed Warning). Steroid therapy ma effective if discontinuation of procainamide does not cause remission of symptoms. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not otherwise controllable, steroid-suppressive therapy may be used concomitantly with procainamide.

Pronestyl Tablets (Procainamide Hydrochloride Tablets) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (includin bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general popu tion is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS: Hypotension is rare with oral administration. Serious disturbances of cardiac rhythm such as ventricular asystole or fibri tion are more common with I.V. administration.

Large oral doses may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported in patie on oral maintenance therapy (see Precautions). Reactions consisting of fev and chills have been reported, including a case with nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloac transaminase following single doses of the drug. Agranulocytosis has been occasionally reported following repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenan procainamide therapy; and the patient should be instructed to report any soreness of the mouth, throat or gums, unexplained fever or any symptom upper respiratory tract infection. If any of these symptoms should occur a leukocyte counts indicate cellular depression, procainamide therapy should discontinued and appropriate treatment should be instituted immediately. ter taste, diarrhea, weakness, mental depression, giddiness, psychosis with hallucinations, and hypersensitivity reactions such as angioneurotic edema maculopapular rash have been reported.

For full prescribing information, consult package insert.

HOW SUPPLIED: Pronestyl Tablets (Procainamide Hydrochloride Table and Pronestyl Capsules (Procainamide Hydrochloride Capsules USP) providing 250 mg, 375 mg, and 500 mg procainamide hydrochloride are availa in bottles of 100 and Unimatic® cartons of 100. The 250 mg and 500 mg tablets and capsules are also available in bottles of 1000.

Raven Press

Ion Transport in Heart
L. J. Mullins
This volume applies the principles of Na/Ca exchange to the transport of ions in heart tissue. Sections discuss carrier-mediated transport, the Na/K pump, Na/Ca exchange, measurements of transport in cardiac cells, interactions between Na/K and Na/Ca pumps, changes in transport during the action potential, depolarization and the generation of tension, and mechanisms for relaxation.
Approximately 125 pp., tentatively $15.00 (March 1981)
ISBN 0-89004-645-X

Stress and the Heart
Second Edition
Editor: D. Wheatley
This revised edition of Stress and the Heart contains updated chapters of the original edition to reflect recent research. New chapters have been added to cover areas that were still uncharted at that time. New subjects include the use of antianxiety drugs in coronary heart disease; beta-adrenergic blocking drugs in stressful situations and in schizophrenia; cardiotoxicity of antidepressants; yoga and biofeedback in hypertension; nootropic drugs; psychopharmacology in the elderly; and sociological aspects of stress.
430 pp., $39.50 (1981) ISBN 0-89004-520-8

Prostaglandins and Cardiovascular Disease
Atherosclerosis Reviews, Vol. 8
Editor: R. J. Hegyeli
This volume reviews our current understanding of the role of prostaglandins in the normal functioning of the cardiovascular system, in a variety of pathologic conditions, and in medical management of these conditions. Current methodologies for conducting research on prostaglandins and cardiovascular disease are highlighted.
220 pp., $25.00 (1981) ISBN 0-89004-516-X

Vasodilatation
Editors: P. M. Vanhoutte and I. Leusen
This volume explores the mechanisms whereby natural regulatory phenomena and synthetic vasodilator agents effect vasodilatation. Section titles are Neurohumoral Regulation, Local Regulation, Cellular Mechanisms, The Blood Vessel Wall in Hypertension, Vasodilator Agents, and Author Index/Subject Index.
Approximately 475 pp., tentatively $46.00 (April 1981)
ISBN 0-89004-602-6

Mechanisms of Cardiac Morphogenesis and Teratogenesis
Perspectives in Cardiovascular Research, Vol. 5)
Editor: T. Pexieder
This volume presents a multidisciplinary analysis of the cellular and subcellular mechanisms regulating cardiac morphogenesis and teratogenesis in the embryo. Sections are: Organogenesis of the Heart, Cell Proliferation, Cell Death, Extracellular Matrix, Cell Surface, Heart Cell Physiology and Interactions, Genetic Control, Epigenetic Control of Cardiac Morphogenesis, and Subject Index.
528 pp., 251 figures, $48.00 (1981) ISBN 0-89004-460-0

Hypertension in Children and Adolescents
Editors: G. Giovannelli, M. I. New, and S. Gorini
This volume provides comprehensive, up-to-date information on the epidemiology, pathogenesis, clinical aspects, and management of childhood and adolescent hypertension. Major sections are: Magnitude of the Problem; Blood Pressure in Childhood and Some Related Aspects; Pathophysiology of Juvenile Hypertension: A. Hypothesis, B. Hemodynamic Aspects, C. Plasma Renin Activity and Sympathetic Nervous System, D. Special Aspects; Clinical Aspects of Juvenile Hypertension; Brief Communications; and Subject Index.
325 pp., $27.00 (1981) ISBN 0-89004-523-2

Central Nervous System Mechanisms in Hypertension
Editors: J. P. Buckley and C. Ferrario
This volume presents the latest interpretations of the contribution of central nervous system mechanisms to the development and the control of hypertension. Major areas covered in depth include the physiological and pharmacological role of the nucleus tractus solitarius in relation to the development and control of elevated arterial pressure; brain renin, angiotensinogen, angiotensin, angiotensin II; and central cardiovascular reflexes.
Approximately 425 pp., tentatively $39.50 (April 1981)
ISBN 0-89004-545-3

CONTENTS

244 **Human Ventricular Refractoriness: Effects of Increasing Current**

ALLAN M. GREENSPAN, JOSEPH S. CAMARDO, LEONARD N. HOROWITZ, SCOTT R. SPIELMAN and MARK E. JOSEPHSON

Examining the relation of refractoriness and current over a range of current strength from 0.1 to 10 mA, these investigators found evidence suggesting that (1) current strength-effective refractory period curves more completely characterize ventricular excitability than does a ventricular effective refractory period at single current strength; and (2) the use of such curves to measure refractoriness may enhance studies of drug effects, alterations of autonomic tone, or reentrant arrhythmias, which may affect or are affected by ventricular refractoriness. These curves in human beings reveal that effective refractory period shortens with increasing current but cannot be used to evaluate the "supernormal" period in the human heart. Since the spatial arrangement of the electrodes may influence the current strength-effective refractoriness relation, this problem requires further examination.

EXPERIMENTAL STUDIES

251 **Extra-Adrenergic Mechanisms Responsible for the Effects of Glucose-Insulin-Potassium Solution on Vulnerability to Ventricular Fibrillation**

WESLEY W. BROOKS, RICHARD L. VERRIER and BERNARD LOWN

These dog experiments confirm that infusion of glucose-insulin-potassium solution protects against ventricular fibrillation in the normal and ischemic canine heart but not during reperfusion after a 10 minute period of coronary arterial occlusion. The protective effect appears to be partly due to the solution's antiadrenergic influence and partly to its cardiac membrane-stabilizing action. The solution's effect was more pronounced than that achieved by beta adrenergic blockade and was not annulled by depletion of cardiac catecholamines. The primary influence is mediated by extra-adrenergic mechanisms.

258 **Lack of Effect of Aspirin on Myocardial Infarct Size in the Dog**

ROBERT O. BONOW, LEWIS C. LIPSON, FLORENCE H. SHEEHAN, NORINE L. CAPURRO, JEFFREY M. ISNER, WILLIAM C. ROBERTS, ROBERT E. GOLDSTEIN and STEPHEN E. EPSTEIN

Although aspirin has been shown to inhibit platelet aggregation and to increase epicardial collateral flow by more than 50 percent, pretreatment with platelet-inhibitory doses of aspirin given intravenously failed to reduce the size of the myocardial infarction after ligation of the left anterior descending coronary artery in 34 foxhounds. Aspirin-treated dogs did not differ from control dogs in percent ventricle at risk, percent infarct weight/left ventricle or percent infarct weight/weight of ventricle at risk.

265 **Regional Myocardial Kinetics of Lidocaine in Experimental Infarction: Modulation by Regional Flow**

RUBEN A. ZITO, VINCENTE J. CARIDE, THEODORE HOLFORD and BARRY L. ZARET

These animal studies demonstrate a highly significant positive linear relation between the relative regional myocardial blood flow and lidocaine tissue concentration in animals killed 1 to 3 minutes but not 5 or more minutes after the injection of lidocaine. The initial distribution of lidocaine after bolus injection is directly proportional to myocardial blood flow within the first 3 minutes of injection; thereafter, the washout of lidocaine appears to be the dominant factor in myocardial distribution. These data show a significant time lag until maximal tissue concentration is reached in poorly perfused myocardium and then a more gradual decrease. This study supports the use of an initial bolus injection of lidocaine together with the double infusion of lidocaine to avoid the initial delay seen with double infusion alone.

METHODS

271 **Noninvasive Methods for Detection of Valve Vegetations in Infective Endocarditis**

ELLEN T. MELVIN, MARVIN BERGER, LETTY G. LUTZKER, EMANUEL GOLDBERG and DONNA MILDVAN

Two dimensional echocardiography (85 percent positive) proved superior, particularly for the identification of aortic and tricuspid valve vegetations, over M mode (49 percent positive), gallium-67 citrate and technitium-99m stannous pyrophosphate cardiac scanning in 35 consecutive episodes of clinically diagnosed endocarditis in 33 patients. No vegetations were detected with technetium-99m stannous pyrophosphate scanning. Only two gallium-67 citrate scans showed cardiac uptake and neither positive study identified the involved heart valve. In both patients valve vegetations were detected only with two dimensional echocardiography.

279 **Pulsed Doppler Echocardiographic Right-Sided Valve Regurgitation. Experimental Results and Clinical Significance**

ALAN D. WAGGONER, MIGUEL A. QUINONES, JAMES B. YOUNG, TEDD A. BRANDON, ABID A. SHAH, MARIO S. VERANI and RICHARD R. MILLER

Studies in 6 dogs and 121 patients demonstrated the value of pulsed Doppler echocardiography as an accurate noninvasive technique for the detection of right-sided valve regurgitation. Increased pressure in the right ventri-

is right for everyone...

which is why Burdick offers a choice.

Like any other professional instrumentation, an exercise tolerance system can be right for one physician and something less (or more) for another. The right choice depends on your practice, preferred protocols, staff, budget, and other considerations.

That's why Burdick offers a choice of ExTOL™ systems to match your needs, without resorting to a combination of components that lack the instrument compatability and one-source serviceability of a Burdick ExTOL system.

We offer three basic exercise tolerance systems with a wide choice of options—single or three-channel cardiographs, single or multi-channel monitors, defibrillators, and our economical TMS-400 or deluxe TMS-300 treadmill with remote control and programmer. In short, we have an ExTOL system that's right for your practice, your particular needs.

For complete information about ExTOL, or a demonstration, call or write
The Burdick Corporation, Milton, Wis. 53563.

LOPRESSOR®
metoprolol tartrate

***Metoprolol exerts a relative preference for beta-one receptors.**

Works where it should— not where it shouldn't— in hypertension

Lopressor represents a refinement in beta-blocker control of hypertension. Only Lopressor exerts a relatively selective effect on beta-one receptors in the heart—those involved in lowering blood pressure—at usual therapeutic levels.

Please see next page for brief summary of prescribing information.

Geigy

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizzine have occurred in about 10 of 100 patients. Depre sion was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficien usually of the Raynaud type; palpitations and cor gestive heart failure have been reported. See **Co traindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has be reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in abou of 100 patients. Nausea, gastric pain, constipatio flatulence, and heartburn have been reported in 100 or less.

Allergic: Pruritus has occurred in less than 1 of 1 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety adverse effects not listed above have been reported with other beta-adrenergic blocking agent and should be considered potential adverse effe of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time an place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respir tory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopresso should be individualized. The usual initial dose is 50 mg twice daily whether used alone or added t diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum ef fect of any given dosage level will be apparent aft one week of therapy. Usual maintenance dosage i approximately 100 mg twice a day, with a range of 100 to 450 mg per day. Dosages above 450 mg p day have not been studied. While twice-daily dosing is effective and can maintain a reduction in blood pressure throughout the day, some patients especially when lower dosages are used, will exp rience a modest rise in blood pressure toward the end of the 12-hour dosing interval. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughou the day. If control is not adequate, a larger dose, three times daily therapy, may achieve better control. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room tem perature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

C79-22 (8/7

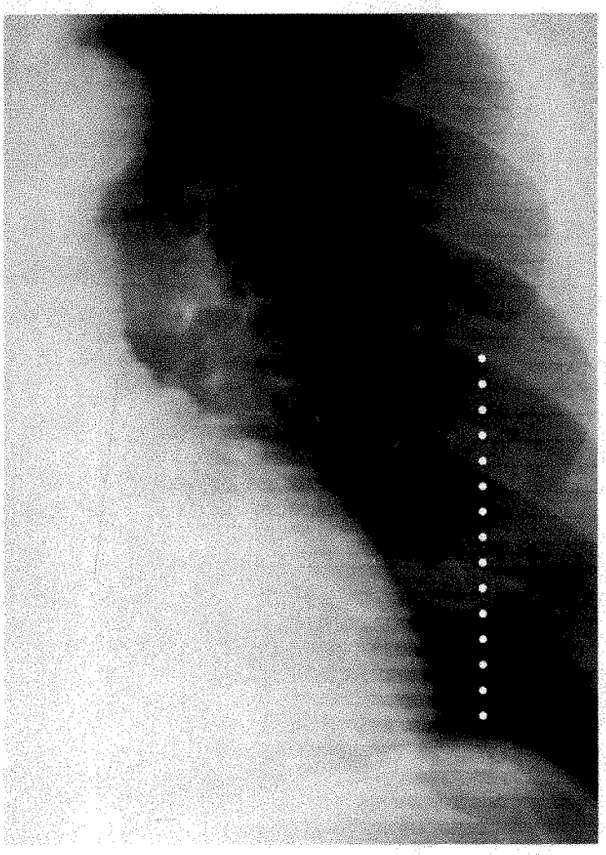
Still the most significant clinical advance in beta-blocker antihypertensive therapy

LOPRESSOR®
metoprolol tartrate

See us at the American College of Cardiology Meeting, San Francisco, Calif. Booth No. 1701

Now you can see coronary artery disease. In a routine X-ray.



IRS x-ray shows an asynergistic contraction. Systolic ›s are marked in this image with white dots, clearly trating normal motion in the basal segment, hypokine- n the lateral wall and paradoxical motion in the apex.

Now there is a simple, accurate technique observing and quantifying ventricular wall ›tion abnormalities: the InterGated™ diography System (IRS), from Brattle. RS works with existing x-ray equipment, olves no major investment, and requires special training to use.

HOW DOES IT WORK?

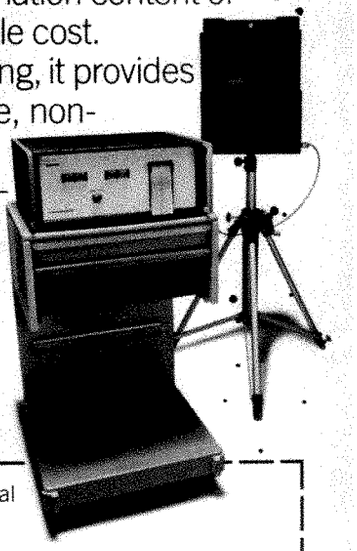
Brattle's IRS produces a serrated cardiac age showing heart motion. The IRS is able to capture the heart at end diastole and end systole during a single cardiac cycle by using ECG-gating. The result is a precise image that can be used to measure and evaluate abnormal heart wall motion, valvular defects and shunts.

Unlike Roentgenkymography, IRS is highly sensitive, highly specific and exposes the patient to no additional radiation.

WHERE IS IT USED?

Brattle's IRS is already in use in hospitals and doctors' offices, where it can dramatically increase the information content of routine x-rays at very little cost.

In addition to screening, it provides physicians with a simple, non-invasive method for monitoring patients during follow-up examination or ECG stress testing.



WANT TO LEARN MORE?

☐ Please send reprints on clinical use of Brattle's InterGated™ Radiography System.

☐ Please contact me to show me some interesting x-rays.

Introducing the Datascope Hospital System.

The most advanced defibrillator system ever put on a crash cart. Or ever taken off one.

Defibrillators for the pital have always been a ıpromise.

Those designed for a crash are difficult to use away from crash cart because they're so vy and unwieldy.

And the portables, while ring more portability, don't e the capability of their vier counterparts.

You've had to choose ween performance and porta- ty. Until now, you couldn't e both.

with you where you need it, when you need it. The support module separates and remains on the crash cart, leaving unnecessary weight behind.

On or off a crash cart, it has features found in no other system.

The scope on the Hospital System is 5″ in diameter. The same size as scopes on defibrillators weighing 35 to 40 pounds.

The monitor offers 2 large digital displays. One for heart

that merely indicates, there's a meter that accurately measure the delivered energy through- out the entire range of the defibrillator.

There's a document switch on the defibrillator paddles to trigger the strip chart recorder. And the paddles rapidly disconnect for easy changes or replacement.

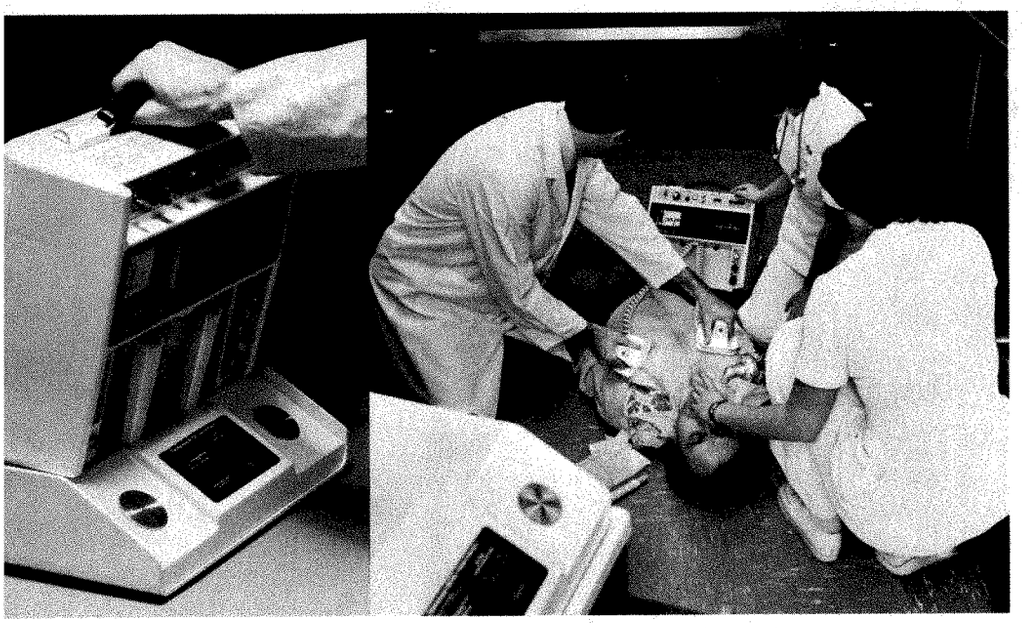
Perhaps the most importar innovation of all, ours is the fir defibrillator system to end the fear of battery failure.

The M/D3 incorporates three totally independent power systems: comple ac line operation, nickel-cadmium batteri that recharge in less tha five hours, and the wor first Lithium Emergenc Power Pack. This revolutionary power pack remains fully- charged in the unit for up to 5 years. In the event that all other pow sources fail, you merel activate the Emergency Pack to instantly powe the monitor and defibrillator.

For all of its features, the M/D3 weighs less than 28 pounds and is extremely easy to operate.

We urge you to see a demonstration of the new Datascope Hospital System. There has never been any defibrillator in a hospital like i On or off a crash cart.

To arrange for a demonstı tion call us at 201-265-8800. Datascope Corp., Box 5-AA, Paramus, NJ 07652. In Europe Datascope B.V., Post Box 26, 3870 CA, Hoevelaken, Hollan



We're pleased to offer you first defibrillator system t doesn't force you to com- mise: the Datascope Hospital stem.

The Datascope Hospital stem is the M/D3 defibrillator/ nitor/recorder and the support dule in which it nests.

Since you may need a ibrillator on a cart, or a table to reach and transport a ient, we designed the M/D3 ike other defibrillators.

The Datascope Hospital stem separates in a manner that kes sense. The defibrillator, nitor and recorder all remain act as a compact unit. So you vays have everything you need

rate and one for delivered energy. (To our mind, lights are simply not an adequate indication of such critical parameters.)

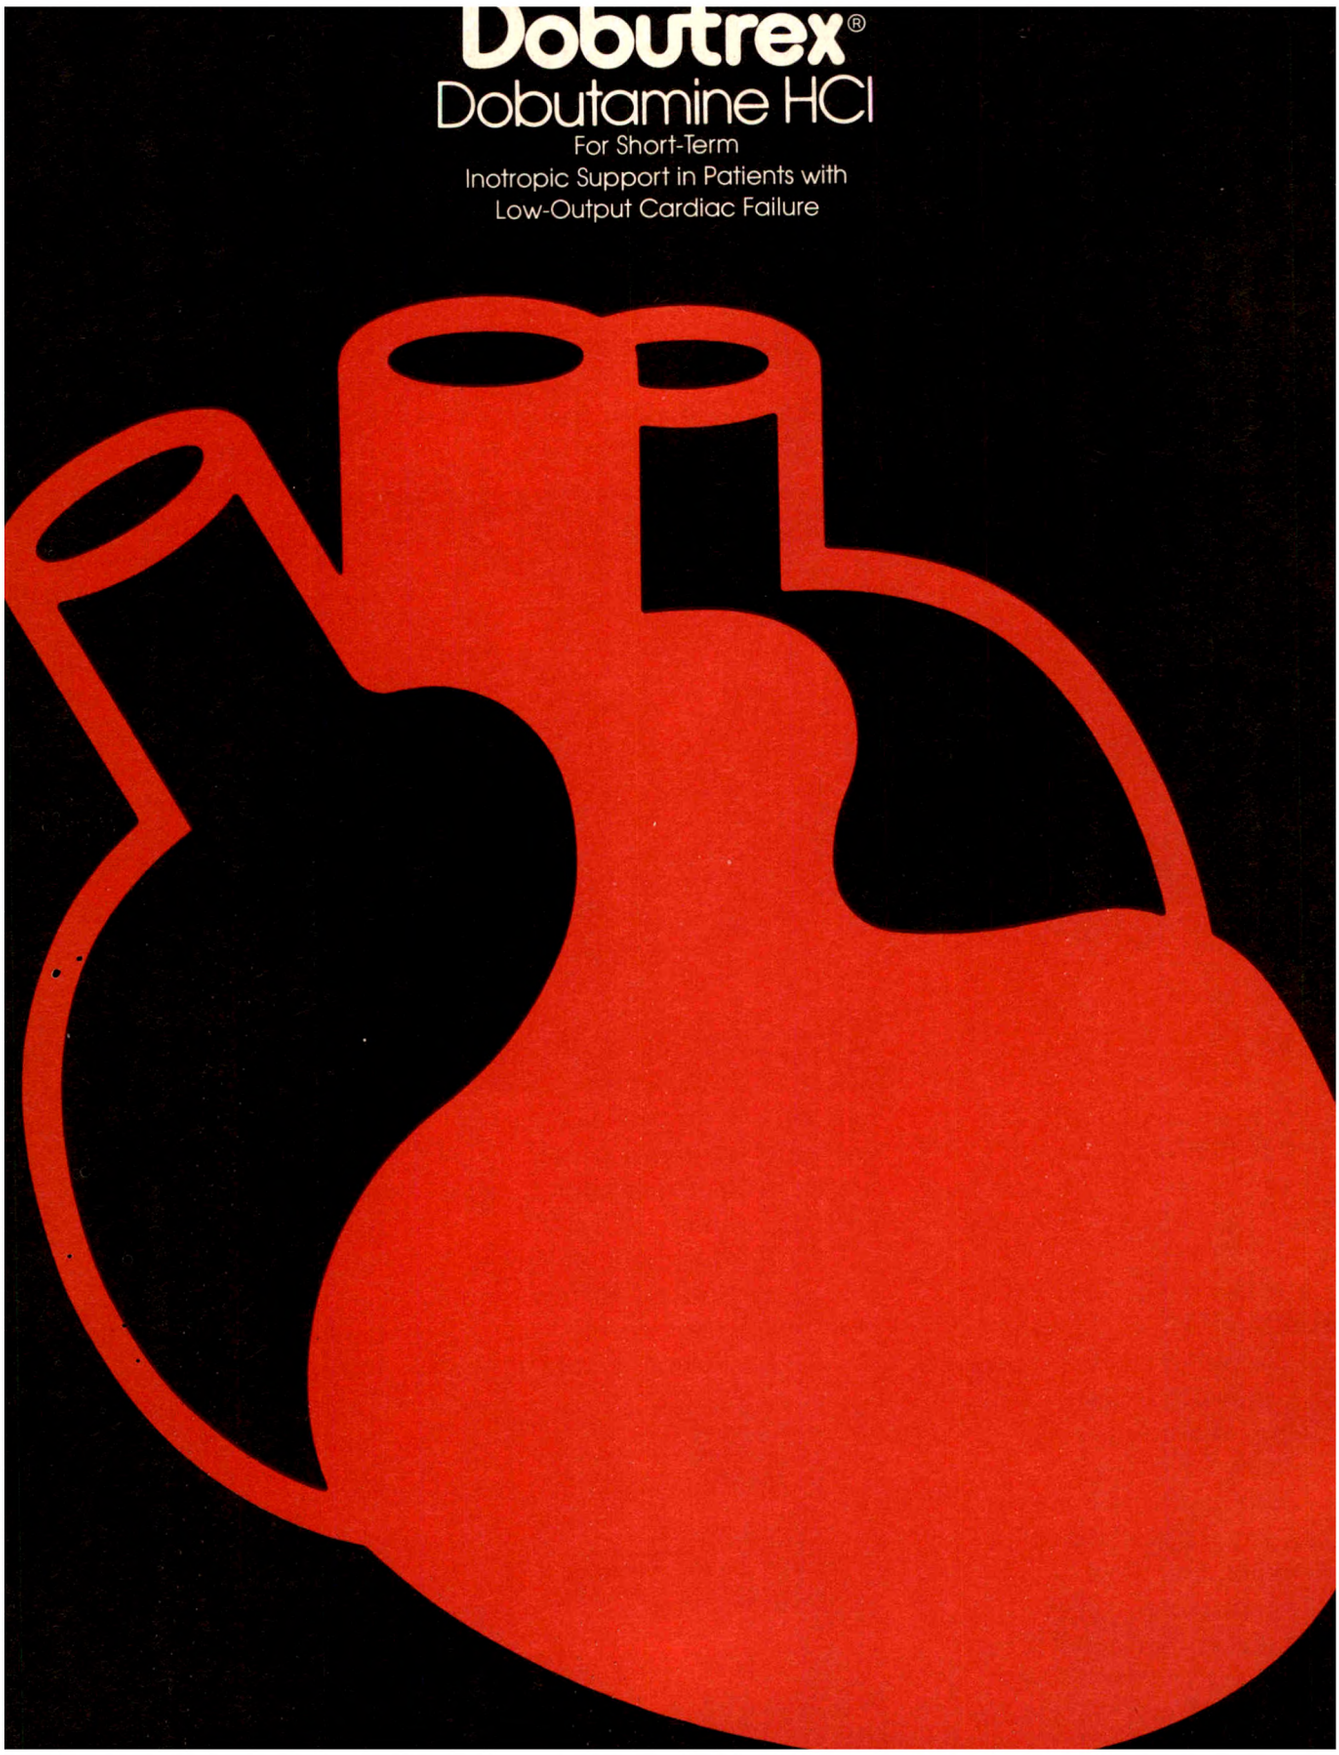
The support module for the Datascope Hospital System has a built-in delivered energy tester. Here again, instead of a light

The Datascope M/D Hospital System

Dobutrex®

Dobutamine HCl

For Short-Term
Inotropic Support in Patients with
Low-Output Cardiac Failure



Selectively Increases
Myocardial Contractility
with Consistent
Hemodynamic Improvements

Dobutrex®
Dobutamine HCl

For I.V. Injection
250 mg* in 20-ml-size vials
* Equivalent to dobutamine

ef Summary
nsult the package literature for prescrib- information.

tications and Usage: Dobutrex® (do- tamine hydrochloride, Lilly) is indicated en parenteral therapy is necessary for in- opic support in the short-term treatment adults with cardiac decompensation due depressed contractility resulting either m organic heart disease or from cardiac gical procedures.
n patients who have atrial fibrillation with oid ventricular response, a digitalis prep- ation should be used prior to instituting rapy with Dobutrex.

ntraindication: Dobutrex is contraindi- ted in patients with idiopathic hyper- phic subaortic stenosis.

rnings: 1. *Increase in Heart Rate or Blood essure*—Dobutrex may cause a marked rease in heart rate or blood pressure, ecially systolic pressure. Approximately 10 rcent of patients in clinical studies have d rate increases of 30 beats/minute or re, and about 7.5 percent have had a -mm Hg or greater increase in systolic essure. Reduction of dosage usually re- rses these effects promptly. Because butamine facilitates atrioventricular con- ction, patients with atrial fibrillation are at of developing rapid ventricular response. tients with preexisting hypertension ap- ar to face an increased risk of developing exaggerated pressor response.
2. *Ectopic Activity*—Dobutrex may precipi- e or exacerbate ventricular ectopic ac- ty, but it rarely has caused ventricular chycardia.

cautions: 1. During the administration of butrex, as with any adrenergic agent, ECG d blood pressure should be continuously nitored. In addition, pulmonary wedge essure and cardiac output should be nitored whenever possible to aid in the fe and effective infusion of Dobutrex.
2. Hypovolemia should be corrected with itable volume expanders before treatment th Dobutrex is instituted.
3. Animal studies indicate that Dobutrex ay be ineffective if the patient has recently ceived a beta-blocking drug. In such a se, the peripheral vascular resistance may crease.
4. No improvement may be observed in e presence of marked mechanical struction, such as severe valvular aortic enosis.
Usage Following Acute Myocardial farction—Clinical experience with Dobu- ex following myocardial infarction has een insufficient to establish the safety of the drug for this use. There is concern that any agent which increases contractile force and heart rate may increase the size of an infarction by intensifying ischemia, but it is not known whether dobutamine does so.

Usage in Pregnancy—Reproduction studies performed in rats and rabbits have revealed no evidence of impaired fertility, harm to the fetus, or teratogenic effects due to dobutamine. However, the drug has not been administered to pregnant women and should be used only when the expected benefits clearly outweigh the potential risks to the fetus.

Pediatric Use—The safety and effectiveness of Dobutrex® (dobutamine hydrochloride, Lilly) for use in children have not been studied.

Drug Interactions—There was no evidence of drug interactions in clinical studies in which Dobutrex was administered concurrently with other drugs, including digitalis preparations, furosemide, spironolactone, lidocaine, glyceryl trinitrate, isosorbide dinitrate, morphine, atropine, heparin, protamine, potassium chloride, folic acid, and acetaminophen. Preliminary studies indicate that the concomitant use of dobutamine and nitroprusside results in a higher cardiac output and, usually, a lower pulmonary wedge pressure than when either drug is used alone.

Adverse Reactions: *Increased Heart Rate, Blood Pressure, and Ventricular Ectopic Activity*—A 10 to 20-mm increase in systolic blood pressure and an increase in heart rate of five to 15 beats per minute have been noted in most patients. (See Warnings regarding exaggerated chronotropic and pressor effects.) Approximately 5 percent of patients have had increased premature ventricular beats during infusions. These effects are dose related.

Miscellaneous Uncommon Effects—The following adverse effects have been reported in 1 to 3 percent of patients: nausea, headache, anginal pain, nonspecific chest pain, palpitations, and shortness of breath.

No abnormal laboratory values attributable to Dobutrex have been observed.

Longer-Term Safety—Infusions of up to 72 hours have revealed no adverse effects other than those seen with shorter infusions.

Overdosage: In case of overdosage, as evidenced by excessive alteration of blood pressure or by tachycardia, reduce the rate of administration or temporarily discontinue Dobutrex until the patient's condition stabilizes. Because the duration of action of Dobutrex is short, usually no additional remedial measures are necessary.

Administration and Dosage: *Reconstitution and Stability*—Dobutrex® (dobutamine hydrochloride, Lilly) is incompatible with alkaline solutions and should not be mixed with products such as 5% Sodium Bicarbonate Injection.

Dobutrex may be reconstituted with Sterile Water for Injection or 5% Dextrose Injection. To reconstitute, add 10 ml of diluent to Vial No. 7051, Dobutrex, 250 mg. If the material is not completely dissolved, add an additional 10 ml of diluent. The reconstituted solution may be stored under refrigeration for 48 hours or at room temperature for six hours.

Reconstituted Dobutrex must be further diluted to at least 50 ml prior to administration in 5% Dextrose Injection, 0.9% Sodium Chloride Injection, or Sodium Lactate Injection. Intravenous solutions should be used within 24 hours.

Solutions containing Dobutrex may exhibit a color that, if present, will increase with time. This color change is due to slight oxidation of the drug, but there is no significant loss of potency during the reconstituted time periods stated above.

Recommended Dosage—The rate of infusion needed to increase cardiac output usually ranges from 2.5 to 10 mcg/kg/min (see table). On rare occasions, infusion rates up to 40 mcg/kg/min have been required to obtain the desired effect.

Rates of Infusion for Concentrations of 250,500, and 1000 mcg/ml

Drug Delivery Rate	Infusion Delivery Rate			
	250 mcg/ml*	500 mcg/ml†	1000 mcg/ml‡	
(mcg/kg/min)	(ml/kg/min)	(ml/kg/min)	(ml/kg/min)	
2.5	0.01	0.005	0.0025	
5	0.02	0.01	0.005	
7.5	0.03	0.015	0.0075	
10	0.04	0.02	0.01	
12.5	0.05	0.025	0.0125	
15	0.06	0.03	0.015	

*250 mg per liter of diluent
†500 mg per liter or 250 mg per 500 ml of diluent
‡1000 mg per liter or 250 mg per 250 ml of diluent

The rate of administration and the duration of therapy should be adjusted according to the patient's response, as determined by heart rate, presence of ectopic activity, blood pressure, urine flow, and, whenever possible, measurement of central venous or pulmonary wedge pressure and cardiac output.

Concentrations up to 5000 mcg/ml have been administered to humans (250 mg/50 ml). The final volume administered should be determined by the fluid requirements of the patient.

cle or pulmonary arteries was present in 90 and 86 percent of patients with Doppler evidence of tricuspid or pulmonary insufficiency, respectively, suggesting a causal relation between high pressure states and mild degrees of right-sided valve regurgitation as detected by pulsed Doppler recording. Because of its high incidence rate (87 percent) and association with pulmonary hypertension (87 percent) pulsed Doppler detection of tricuspid or pulmonary insufficiency, or both (in the absence of pulmonary stenosis) was found superior to M mode electrocardiographic measurements and clinical auscultation in the prediction of pulmonary hypertension.

287 **Quantification of Valve Regurgitation by Radionuclide Angiography Before and After Valve Replacement Surgery**

JOANN URQUHART, RANDOLPH E. PATTERSON, MILTON PACKER, STANLEY J. GOLDSMITH, STEVEN F. HOROWITZ, ROBERT LITWAK and RICHARD GORLIN

This study validates the use of the stroke index ratio determined with radionuclide angiocardiography as a noninvasive estimate of the magnitude of valve regurgitation in 20 patients with aortic or mitral valve disease, or both. This ratio was higher in patients with aortic and mitral regurgitation than in a control group of 10 patients without regurgitation. After aortic and mitral valve replacement in 18 patients, the stroke index ratio decreased from 4.03 ± 1.46 to 1.38 ± 0.23, not significantly different from that in patients without regurgitation. These data establish a linear relation between the index and quantitative calculations of the regurgitant factor in man. A stroke ratio index of greater than 1.62 indicates significant valve regurgitation preoperatively and suggests residual regurgitation postoperatively. These data substantiate the value of radionuclide angiography as a noninvasive method of detecting and quantifying the magnitude of left-sided valve regurgitation by comparing left ventricular and right ventricular systolic and diastolic counts.

292 **Radionuclide Regurgitant Index: Value and Limitations**

WILFRED LAM, DAN PAVEL, ERNEST BYROM, AMJAD SHEIKH, DAVID BEST and KENNETH ROSEN

In this study of 100 patients with left-sided valve regurgitation graded angiographically, the radionuclide regurgitant index (left ventricular/right ventricular stroke counts obtained from gated equilibrium study) was 2.9 to 1.5 in 51 patients, 1.6 to 2.4 in 23 and 2.5 to 12.0 in 26. The index significantly differed between patients with no regurgitation and each group with regurgitation and between groups with regurgitation separated by two or more grades of angiographic regurgitation. A discordant (or spurious) regurgitant index was found in 12 patients with a markedly reduced left ventricular ejection fraction or mitral valve prolapse with frequent ventricular extrasystoles. Recognizing this potential source of error should make the radionuclide regurgitant index more useful for assessing the presence and severity of left-sided valve regurgitation.

PEDIATRIC CARDIOLOGY

299 **Treatment of d-Transposition of the Great Arteries: Management of Hypoxemia After Balloon Atrial Septostomy**

CATHERINE G. HENRY, DAVID GOLDRING, ALEXIS F. HARTMAN, CLARENCE S. WELDON and ARNOLD W. STRAUSS

In a group of 43 patients with d-transposition of the great arteries who underwent Rashkind balloon atrial septostomy at the time of initial catheterization, 88 percent survived to the time of intraatrial baffle repair between 6 and 12 months and 72 percent were long-term survivors. Prostaglandin E_1 infusion proved life-saving and provided sufficient palliation in patients with persistent hypoxemia and acidosis after balloon atrial septostomy. In these patients, discontinuation of prostaglandin E_1 infusion resulted in return of oxygen saturation to preinfusion levels but no further metabolic acidosis. As a consequence of their experiences these investigators provided the following guidelines for early management of patients with transposition of the great vessels: (1) balloon atrial septostomy and conservative medical management for all patients without acidosis regardless of oxygen saturation following Rashkind septostomy, (2) prostaglandin E_1 infusion, and (3) early Senning or Mustard intraatrial baffle repair.

307 **Results of Intraventricular Baffle Procedure for Ventricular Septal Defect and Double Outlet Right Ventricle or d-Transposition of the Great Arteries**

PAUL PITLICK, JAMES FRENCH, DIANA GUTHANER, NORMAN SHUMWAY and DAVID BAUM

In this group of 30 patients with ventricular septal defect and d-transposition of the great arteries or double outlet right ventricle who underwent placement of an intraventricular baffle to achieve physiologic correction there was an overall 22 percent early mortality rate and an additional 20 percent mortality rate primarily related to problems of conduction disturbances and pulmonary vascular obstructive disease. These problems have not occurred in patients operated on since 1974. In this series small patient size was the major factor related to early mortality. The risk of surgical death was 7 times higher in patients who weighed less than 10 kg than in patients who weighed more than 10 kg. All 17 current survivors are asymptomatic, and many show significant weight gain. In spite of the problems associated with the intraventricular baffle procedure, the investigators believe that the overall improvement outweighs the risks of the procedure and present their guidelines for surgical intervention.

You May Be Mis-Diagnosing Your Holter Patients.

The incompleteness of Holter scan reports with unverifiable numbers and trends are the reasons. Less than 1% of the Holter ECG data is normally presented for your diagnosis. What happened the other 99% of the time?

1979 brought a breakthrough in Holter monitoring. The development of micro-computer controlled fiberoptics made it possible to print every ECG complex into a textbook format, providing twenty-four, hourly pages of ECG data.

No matter who the operator, the report is identical every time, and only takes three minutes to generate. Plus, this report is faster and easier to read than that of conventional Holter equipment.
The major difference is "Assurance".

The product is The Eliminator™ by AdvanceMed, now a part of American Hospital Supply Corporation. The Eliminator is the first to offer 100% accurate ECG data and is available at half the price of average Holter equipment.

You owe it to yourself and to your patients to see The Eliminator. Since it is compatible with most Holter recording systems, call or write and we'll run one of your tapes.
You May Be Surprised To See What You Are Missing!

American Edwards / AdvanceMed, 1923 SE Main Street, Irvine, California 92714, (714) 751-1824. (800) 854-8081.

CONTENTS

315 **Idiopathic Recurrent Sustained Ventricular Tachycardia in Children and Adolescents**

VICTORIA L. VETTER, MARK E. JOSEPHSON and LEONARD N. HOROWITZ

Electrophysiologic studies of recurrent sustained ventricular tachycardia in 7 pediatric patients confirm that tachycardia was more frequently due to an automatic than to a reentrant mechanism, originated more often in the right ventricle and was infrequently associated with structural heart disease. One patient had a coronary arterial abnormality of undetermined significance; six had normal angiographic and hemodynamic studies. Ventricular tachycardia was infrequently initiated and terminated by programmed electrical stimulation. These differences in the frequency of the reentrant mechanism of ventricular tachycardia in children and adults as well as the differences in the anatomic substrate necessitate differences in evaluation and therapy of ventricular arrhythmias in these age groups.

323 **Clinical Course of Cardiovascular Involvement in the Mucocutaneous Lymph Node Syndrome. Relation Between Clinical Signs of Carditis and Development of Coronary Arterial Aneurysm**

SATOSHI HIRAISHI, KIMIO YASHIRO, KOKI OGUCHI, SHOICHI KUSANO, KATSUMI ISHII and KEIJI NAKAZAWA

Data collected in 79 Japanese children with the mucocutaneous lymph node syndrome revealed the presence of myocarditis in 50.6 percent during stages I and II and of one or more coronary aneurysms in 11 patients primarily in stage II. Regression of the aneurysm was noted in five of these patients later during stages III, IV and V. Regression of aneurysms demonstrated angiographically does not imply complete recovery of the coronary artery because it may result from a reduction of the internal lumen due to some pathologic mechanism. The occurrence of coronary aneurysm did not correlate with the presence of clinical signs of carditis. The frequency of carditis was the same in patients with and without aneurysm. This study therefore shows no distinct relation between coronary aneurysm formation and clinical carditis.

REPORTS ON HYPERTENSION

331 **Platelet Function in Hypertension and Effect of Therapy**

JAWAHAR MEHTA and PAULETTE MEHTA

Evaluation of platelet function in 10 hypertensive and 11 normal subjects suggests that enhanced platelet activation in primary hypertension may be associated with increased vascular resistance. The levels of plasma beta thromboglobulin (the secretory product of platelets released by their alpha granules during the release reaction) were significantly increased in certain patients with hypertension. After blood pressure was controlled with lofexidine, plasma beta thromboglobulin levels decreased in 9 of the 10 hypertensive patients but increased in 1 with no change in blood pressure. Further studies are needed to determine whether such inhibition of platelet activation with platelet-suppressive agents ameliorates any of the clinical sequelae in hypertensive patients.

335 **Clinical Correlates in Hypertensive Patients With Left Ventricular Hypertrophy Diagnosed With Echocardiography**

ANDRÉ COHEN, ARTHUR D. HAGAN, JOHN WATKINS, JOHN MITAS, MARIO SCHVARTZMAN, ALBERTO MAZZOLENI, IRVING M. COHEN, S. E. WARREN, and W. V. R. VIEWEG with the technical assistance of WILLIAM ELIAS and LINDA SAMTOY

M mode and two dimensional echocardiography in 73 hypertensive patients revealed left ventricular hypertrophy (using a posterior wall thickness of 12 mm as the criterion) in 37 patients (51 percent); 29 had concentric hypertrophy and 8 had disproportionate septal thickening. Electrocardiography proved insensitive in identifying left ventricular hypertrophy in these patients. The presence of increased left ventricular mass was associated with a greater incidence of other target organ disease, resulting in stroke, hypertensive retinopathy, impaired renal function and elevated serum creatinine. Ten percent had decreased left ventricular performance evidenced by fractional shortening of less than 31 percent and mild diffuse hypokinesia on two dimensional studies.

REVIEWS

343 **Clinicopathologic Correlates of Acute Ischemic Heart Disease Syndromes**

L. MAXIMILIAN BUJA and JAMES T. WILLERSON

This clinicopathologic review of 100 recent myocardial infarct in 83 patients demonstrates that acute ischemic heart disease has no constant relation with the severity of chronic atherosclerosis. Myocardial necrosis, usually limited to subendocardial involvement, commonly occurs in the absence of acute coronary occlusion. Acute coronary thrombosis frequently determines the extent and distribution of an evolving infarct. Coronary thrombus formation does not depend on a generalized impairment or coronary perfusion either before or after the onset of infarction. The frequent association of coronary thrombosis with plaque erosion, rupture and hemorrhage strongly suggests that the key initiating event in thrombus formation occurs in the coronary artery. The clinical

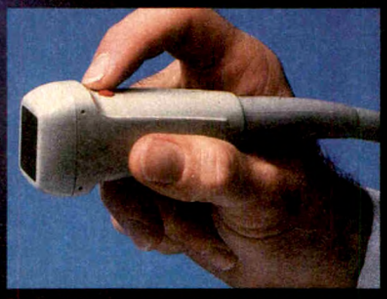
THE IMAGE QUALITY IS EVERYTHING YOU'D EXPECT FROM HEWLETT-PACKARD

Compact, cart-mounted mobile system is ideal for the cardiology lab as well as coronary care units.

Now you can get a full-featured, real time, phased array, two-dimensional scanner that offers meaningful technological advances in almost every area.

It's the real time scanner for echocardiography from Hewlett-Packard. Incorporating a small 64-element array transducer, innovations in signal processing, microcomputer-based circuitry and a new digital scan converter, the HP system not only provides superior image quality, it does it at a price



Small, lightweight, handheld transducer minimizes operator fatigue and fits easily in difficult locations.

that compares favorably to conventional mechanical scanners.

Superb resolution for accurate diagnosis.

The HP Ultrasound Imaging System provides extraordinarily high resolution images at all depths throughout the field of view. Its wide aperture, small electronic array transducer and automatic focusing technique give you extremely accurate images—even in areas near the transducer and deep in the body. And since the entire field of view is in focus at all times, you can see shallow as well as deep structures in the same picture. The compact, lightweight transducer fits in intercostal spaces and enhances the scanning of the heart.

Built-in self-test capability assures the operator that everything is functioning properly.

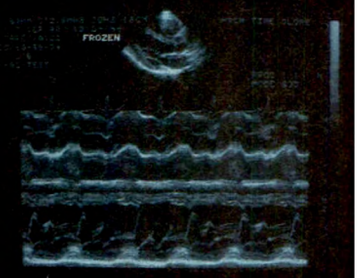
A new method of digital scan conversion eliminates radial scan lines, moiré patterns and blocky digital artifacts, and results in an accurate image. A total of 30 shades of gray can be processed, so small variations in tissue density can be distinguished.

Quantitative analysis on both the M-mode and two-dimensional image is accomplished by an electronic cursor.

The wide dynamic range of the system's circuitry produces a sharp image, while reducing background noise and clutter. The system's high-resolution, high-speed (twice the conventional TV rate) display gives you an easy-to-see, flicker-free picture that can be taped and replayed on standard video equipment.

Simple, centralized controls for easy operation.

With the HP scanner, you not only get superior image quality, you get it quickly and easily. All major controls are logically located in one central area. You can scan patient after patient with a minimum of control adjustments. The HP scanner even provides a built-in self-test capability, so you know that everything is functioning properly.



M-mode is easily visualized on the same screen as the two-dimensional sector.

All this and more, for less.

While the HP scanner delivers exceptional image quality and easy operation, it doesn't compromise features. It offers quantitative analysis capabilities, ECG triggering, and "freeze-frame." You can view the sector scan and the M-mode display on the same screen simultaneously. In addition, the dual M-mode display lets you analyze two areas of the heart at the same time.

For more information on this full-featured, surprisingly affordable HP Model 77020A Ultrasound Imaging System for echocardiography, call your local Hewlett-Packard sales office, or write: Wayne Wager, Hewlett-Packard, 175 Wyman Street, Waltham, MA 02254.

HEWLETT PACKARD

17003

onset of infarction was followed by severe cardiac pump failure or congestive heart failure in 63.9 percent of infarcts associated with and 41 percent of infarcts not associated with recent occlusion. Acute events can be precipitated by factors that increase myocardial oxygen demand or reduce cardiac or coronary reserve. Additional factors of potential importance include platelet alterations, imbalance in the prostacyclin-thromboxane A_2 system and altered adrenergic function and the probable influence of these factors on induction of coronary arterial spasm.

357 **Response of the Left Ventricle to Stress: Effects of Exercise, Atrial Pacing, Afterload Stress and Drugs**

ROBERT SLUTSKY

This review summarizes the response of left ventricular performance and size to atrial pacing, afterload stress and various forms of exercise in normal subjects and subjects with coronary heart disease. Most testing methods include aerobic and anaerobic exercise as well as the infusion of agents that alter preload, afterload and inotropic states. Many exercise-induced abnormalities in left ventricular size and function of patients with coronary artery disease may be reversed by pretreating the patient with sublingual nitroglycerin or nitroglycerin paste before the exercise study. Atrial pacing reduces cardiac size in normal subjects with little change in ejection fraction, cardiac output or peripheral vascular resistance. Velocity indexes increase. In patients with ischemic heart disease ventricular volume declines, ejection fraction decreases or remains unchanged and new wall motion abnormalities may appear. Cardiac output does not change because stroke volume declines in proportion to the increase in heart rate. In both normal subjects and subjects with heart disease isoproterenol infusions reduce systemic vascular resistance, increase cardiac output and index and increase ejection fraction with a reduction in both end-diastolic and end-systolic volumes.

DIAGNOSTIC SHELF

365 **Echocardiographic Mimicry of Pericardial Effusion**

PATRICIA C. COME, MARILYN F. RILEY and NICHOLAS J. FORTUIN

Abnormal echocardiographic patterns mimicking pericardial effusions were revealed in four patients in whom anatomic structure, a coronary artery to coronary sinus fistula (one case) and metastatic tumors to the pericardium (three cases) produced posterior or anterior spaces compatible with pericardial fluid. Since an improper echocardiographic diagnosis of pericardial effusion may result in unwarranted pericardiocentesis or more aggressive surgical procedures, appropriate attention must be paid to recognition of technical artifacts and other anatomic conditions that mat simulate pericardial effusion. Two dimensional echocardiography may enhance the diagnosis.

371 **"Supernormal" Phase of Atrioventricular Conduction With Concealed Capture Beats. Significance of Odd Number of P Waves Between Capture Beats**

ALAN LINDSAY and LEO SCHAMROTH

These two case reports are of special interest because they reflect for the first time concealed supernormal atrioventricular (A-V) nodal penetration and confirm a mathematical hypothesis previously propounded to explain this particular manifestation of A-V nodal supernormality on the basis of differential horizontal refractoriness.

the drawbacks of using retrospective evidence and call for the formation of a multi-center, double-blind, randomized study on the use of anticoagulants in acute myocardial infarction.

Screening the high risk group The risk of DVT (deep vein thrombosis) is particularly great among certain patient groups:

- patients with left ventricular failure
- patients in shock
- patients with arrhythmias
- older patients
- obese patients
- patients with varicose veins
- patients with previous myocardial infarction or thromboembolism

Screening techniques Diagnosis of DVT by physical examination may miss a significant number of clinically silent thrombi. There are, however, additional technological tools to help the clinician define more accurately the incidence of deep vein thrombosis. Among these are:

iodine-125 fibrinogen scanning—radioactively tagged fibrinogen is incorporated into actively forming thrombi and is detected on external sensors. This method is accurate for popliteal and calf vein thrombi, but not for iliofemoral thrombi.[2]

Phlebogram showing occlusion in deep vein of the upper calf.

venography—radiographic evidence of DVT is seen as a constant filling defect in venous projections, abrupt termination of a column of contrast material at a constant site, nonfilling of the deep veins, and presence of flow in collateral veins.[4]

ultrasound—Doppler ultrasound scanning can provide a fast, convenient, inexpensive reading of deep venous obstruction. This technique is potentially the most versatile and accurate method available. However, it demands considerable operator experience to insure maximal accuracy.[5]

impedance plethysmography—this technique results from the observation that blood volume changes in the calf produced by inflation or deflation of a thigh cuff produce variations in electrical resistance (impedance). Such changes are reduced in patients with thrombosis of the popliteal or more proximal veins.[4]

Patient compliance through education Providing the anticoagulated patient with information about his altered physical state and motivating him to comply with the therapeutic regimen constitute one of the most important aspects of health care.[6]

To determine the best way of imparting necessary information about anticoagulation to patients, a test was devised. One group of patients was given a brochure detailing the need for the medication and the importance of following the doctor's instructions. A second group of patients was given a programmed instruction booklet which was quite comprehensive in its teaching content, which included the action of warfarin, the purpose of prothrombin times, how to figure dosage from tablet strengths, possible complications and steps to take to control them.

When tested for learning and retention, the patients in the programmed instruction group scored significantly higher than the group given brochures only. In an area of medicine that relies so heavily on patient compliance, this report could be important in determining how medical information is communicated to the patient.[6]

The bottom line A postmortem study[7] underlines the importance of thrombosis in myocardial infarction. In this study of 173 patients with recurrent myocardial infarction, coronary occlusion due to thrombosis occurred in 54% of cases. Recent occlusive coronary thrombosis was 4 times less frequent in patients who received adequate anticoagulation (mean prothrombin level was 29 ± 5%).

And as one authority states:

"Rational use of anticoagulant therapy in the setting of acute myocardial infarction may save more than 8,000 lives a year in this country. Full advantage should be taken of this therapeutic opportunity."[2]

For prescribing information on COUMADIN® (crystalline warfarin sodium) tablets, including information relating to side effects and contraindications, please see full prescribing information on the following page.

COUMADIN®

crystalline warfarin sodium, U.S.P.*

TABLETS

DESCRIPTION COUMADIN (crystalline warfarin sodium), a prothrombinopenic anticoagulant, is chemically crystalline sodium warfarin isopropanol clathrate. The crystallization of warfarin sodium virtually eliminates trace impurities present in amorphous warfarin sodium, thus achieving a crystalline product of the highest purity. Warfarin* is the coined generic name for 3-(α-Acetonylbenzyl)-4-hydroxycoumarin. On a dose-for-dose basis, COUMADIN (crystalline warfarin sodium) is therapeutically equivalent to amorphous warfarin sodium.

ACTIONS COUMADIN and other coumarin anticoagulants act by depressing synthesis in the liver of several factors which are known to be active in the coagulation mechanisms in a variety of diseases characterized by thromboembolic phenomena. The resultant **in vivo** effect is a sequential depression of Factors VII, IX, X and II. The degree of depression is dependent upon the dosage administered. Anticoagulants have no direct effect on an established thrombus, nor do they reverse ischemic tissue damage. However, once a thrombosis has occurred, anticoagulant treatment aims to prevent further extension of the formed clot and prevents secondary thromboembolic complications which may result in serious and possible fatal sequelae.

After oral administration, absorption is essentially complete, and maximal plasma concentrations are reached in 1 to 9 hours. Approximately 97% is bound to albumin within the plasma. COUMADIN (crystalline warfarin sodium) usually induces hypoprothrombinemia in 36 to 72 hours, and its duration of action may persist for 4 to 5 days, thus producing a smooth, long lasting response curve. Little is known of the metabolic pathways involved in the biotransformation of oral anticoagulants in man. However, their metabolites appear to be eliminated principally in the urine.

INDICATIONS Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: COUMADIN is indicated for the prophylaxis and treatment of venous thrombosis and its extension, the treatment of atrial fibrillation with embolization, the prophylaxis and treatment of pulmonary embolism, and as an adjunct in the treatment of coronary occlusion.

"Possibly" effective: as an adjunct in the treatment of transient cerebral ischemic attacks.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATIONS Anticoagulation is contraindicated in any localized or general physical condition or personal circumstance in which the hazard of hemorrhage might be greater than its potential clinical benefits, such as:

Pregnancy—COUMADIN (crystalline warfarin sodium) is contraindicated in pregnancy because the drug passes through the placental barrier and may cause fatal hemorrhage to the fetus in utero. Furthermore, there have been reports of birth malformations in children born to mothers who have been treated with warfarin during pregnancy. Women of childbearing potential who are candidates for anticoagulant therapy should be carefully evaluated and the indications critically reviewed with the patient. If the patient becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus, and the possibility of termination of the pregnancy should be discussed in light of those risks.

Hemorrhagic tendencies or blood dyscrasias. Recent or contemplated surgery of: (1)central nervous system; (2)eye; (3)traumatic surgery resulting in large open surfaces. **Bleeding tendencies associated with active ulceration or overt bleeding of:** (1)gastrointestinal, genitourinary or respiratory tracts; (2)cerebrovascular hemorrhage; (3)aneurysms—cerebral, dissecting aorta; (4)pericarditis and pericardial effusions; (5)subacute bacterial endocarditis. **Threatened abortion,** eclampsia and preeclampsia. **Inadequate laboratory facilities** or unsupervised senility, alcoholism, psychosis, or lack of patient cooperation. **Spinal puncture** and other diagnostic or therapeutic procedures with potential for uncontrollable bleeding. **Miscellaneous:** major regional, lumbar block anesthesia and malignant hypertension.

WARNINGS Warfarin sodium is a potent drug with a half-life of 2½ days; therefore its effects may become more pronounced as daily maintenance doses overlap. It cannot be emphasized too strongly that treatment of each patient is a highly individualized matter. Dosage should be controlled by periodic determinations of prothrombin time or other suitable coagulation tests. Determinations of whole blood clotting and bleeding times are not effective measures for control of therapy. Heparin prolongs the one-stage prothrombin time. Therefore, to obtain a valid prothrombin time when heparin and COUMADIN (crystalline warfarin sodium) are given together, a period of at least 5 hours should elapse after the last intravenous dose and 24 hours after the last subcutaneous dose of heparin, before blood is drawn.

Caution should be observed when warfarin sodium is administered in any situation or physical condition where added risk of hemorrhage is present.

Administration of anticoagulants in the following conditions will be based upon clinical judgment in which the risks of anticoagulant therapy are weighed against the risk of thrombosis or embolization in untreated cases. The following may be associated with these increased risks:

Lactation—Coumarins may pass into the milk of mothers and cause a prothrombinopenic state in the nursing infant. **Severe to moderate hepatic or renal insufficiency. Infectious diseases or disturbances of intestinal flora**—sprue, antibiotic therapy. **Trauma** which may result in internal bleeding. **Surgery or trauma** resulting in large exposed raw surfaces. **Indwelling catheters. Severe to moderate hypertension. Miscellaneous:** polycythemia vera, vasculitis, severe diabetes, severe allergic and anaphylactic disorders.

Patients with congestive heart failure may become more sensitive to COUMADIN, thereby requiring more frequent laboratory monitoring, and reduced doses of COUMADIN.

Concurrent use of anticoagulants with streptokinase or urokinase is not recommended and may be hazardous. (Please note recommendations accompanying these preparations.)

Abrupt cessation of anticoagulant therapy is not generally recommended; taper dose gradually over three to four weeks.

PRECAUTIONS Periodic determination of prothrombin time or other suitable coagulation test is essential.

Numerous factors, alone or in combination, including travel, changes in diet, environment, physical state and medication may influence response of the patient to anticoagulants. It is generally good practice to monitor the patient's response with additional prothrombin time determinations in the period immediately after discharge from the hospital, and whenever other medications are initiated, discontinued or taken haphazardly. The following factors are listed for your reference; however, other factors may also affect the prothrombin response.

The following factors, alone or in combination, may be responsible for increased prothrombin time response:

ENDOGENOUS FACTORS: Carcinoma; collagen disease; congestive heart failure; diarrhea; elevated temperature; hepatic disorders—infectious hepatitis, jaundice; poor nutritional state; vitamin K deficiency—steatorrhea.

EXOGENOUS FACTORS: Alcohol†; allopurinol; aminosalicylic acid; anabolic steroids; antibiotics; bromelains; chloral hydrate†; chlorpropamide; chymotrypsin; cimetidine; cinchophen; clofibrate; COUMADIN (crystalline warfarin sodium) overdosage; dextran; dextrothyroxine; diazoxide; dietary deficiencies; diuretics†; disulfiram; drugs affecting blood elements; ethacrynic acid; glucagon; hepatotoxic drugs; indomethacin; inhalation anesthetics; mefenamic acid; methyldopa; methylphenidate; metronidazole; monoamine oxidase inhibitors; nalidixic acid; oxolinic acid; oxyphenbutazone; pyrazolones; phenylbutazone; phenyramidol; phenytoin; prolonged hot weather; prolonged narcotics; quinidine; quinine; salicylates; sulfinpyrazone; sulfonamides, long acting; sulindac; thyroid drugs; tolbutamide; triclofos sodium; trimethoprim/sulfamethoxazole; unreliable prothrombin time determinations.

*Present as crystalline sodium warfarin isopropanol clathrate.

†Increased and decreased prothrombin time responses have been reported.

COUMADIN is an Endo registered U.S. trademark.

ENDO-924C Printed in U.S.A. Nov. 1980

The following factors, alone or in combination, may be responsible for decreased prothrombin time response:

ENDOGENOUS FACTORS: Edema; hereditary resistance to coumarin therapy; hyperlipemia; hypothyroidism.

EXOGENOUS FACTORS: Adrenocortical steroids; alcohol†; antacids; antihistamines; barbiturates; chloral hydrate†; chlordiazepoxide; cholestyramine; COUMADIN (crystalline warfarin sodium) underdosage; diet high in vitamin K; diuretics†; ethchlorvynol; glutethimide; griseofulvin; haloperidol; meprobamate; oral contraceptives; paraldehyde; primidone; rifampin; unreliable prothrombin time determinations; vitamin C.

†Increased and decreased prothrombin time responses have been reported.

A patient may be exposed to a combination of the above factors, some of which may increase and some decrease his sensitivity to COUMADIN. Because the net effect on his prothrombin time response may be unpredictable under these circumstances, more frequent laboratory monitoring is advisable.

Drugs not yet shown to interact or not to interact with coumarins are best regarded with suspicion, and when their administration is started or stopped, the prothrombin time should be determined more often than usual.

Coumarins also affect the action of other drugs. Hypoglycemic agents (chlorpropamide and tolbutamide) and anticonvulsants (phenytoin and phenobarbital) may accumulate in the body as a result of interference with either their metabolism or excretion.

ADVERSE REACTIONS Potential side effects of COUMADIN (crystalline warfarin sodium) include:

1. Minor or major hemorrhage from any tissue or organ—which is an extension of the physiologic activity of prothrombinopenia. The signs and symptoms will vary according to the location and degree or extent of the bleeding. Therefore the possibility of hemorrhage should be considered in evaluating the condition of any anticoagulated patient with complaints which do not indicate an obvious diagnosis. Bleeding during anticoagulant therapy does not always correlate with prothrombin activity. (See TREATMENT FOR OVERDOSAGE.)

Bleeding which occurs when the prothrombin time is within the therapeutic range warrants diagnostic investigation since it may unmask a previously unsuspected lesion, e.g. tumor, ulcer, etc.

2. Side effects other than hemorrhage are infrequent and consist of alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramping, a syndrome called "purple toes," hypersensitivity reactions and a reaction consisting of hemorrhagic infarction and necrosis of the skin.

3. Priapism has been associated with anticoagulant administration, however, a causal relationship has not been established.

DOSAGE AND LABORATORY CONTROL The aim of anticoagulant therapy is to impede the coagulation or clotting mechanism to such an extent that thrombosis will not occur, but at the same time avoiding such extensive impairment as might produce spontaneous bleeding. Effective therapeutic levels with minimal complications can best be achieved in cooperative and well-instructed patients, who keep the doctor informed of their status between visits. COUMADIN (crystalline warfarin sodium) patient aids are available to physicians on request.

The administration and dosage of COUMADIN must be individualized for each patient according to the particular patient's sensitivity to the drug as indicated by the prothrombin time. The prothrombin time reflects the depression of vitamin K dependent Factors VII, X and II. These factors, in addition to Factor IX, are affected by coumarin anticoagulants. There are several modifications of the Quick one-stage prothrombin time and the physician should become familiar with the specific method used in his laboratory.

Administration of COUMADIN should be gauged according to prothrombin time determinations by a suitable method. The blood prothrombin time should usually be determined daily after the administration of the initial dose until prothrombin time results stabilize in the therapeutic range. Intervals between subsequent prothrombin time determinations should be based upon the physician's judgment of the patient's reliability and response to warfarin in order to maintain the individual within the therapeutic range. Acceptable intervals for prothrombin time determinations have usually fallen within the range of one to four weeks. Satisfactory levels for maintenance of therapeutic anticoagulation are 1½ to 2½ times the normal prothrombin time (e.g. 18 to 30 seconds, with a control of 12 seconds).

Induction—40 to 60 mg for average adult or 20 to 30 mg for elderly and/or debilitated patients for one dose only administered orally, intravenously or intramuscularly.

Alternatively, the large priming dose may be decreased for all patients to minimize the possibility of excessive increases in prothrombin time. Induction may be initiated with 10 to 15 mg daily and thereafter (usually 2 or 3 days) adjusted according to prothrombin time response. The basis for the no-loading dose regimen is that the depression of Factors II, IX, and X is not accelerated by the administration of a loading dose.

Maintenance—Most patients are satisfactorily maintained at a dose of 2 to 10 mg daily. Flexibility of dosage is provided by breaking scored tablets in half. The individual dose and interval should be gauged by the patient's prothrombin response.

Duration of therapy—The duration of therapy in each patient should be individualized. In general, anticoagulant therapy should be continued until the danger of thrombosis and embolism has passed.

Treatment during dentistry and surgery—The management of patients who undergo dental and surgical procedures requires close liaison between attending physicians, surgeons and dentists. Interruption of anticoagulant therapy may precipitate thromboembolism, and conversely, if anticoagulants are maintained at full doses, some patients may hemorrhage excessively. If it is elected to administer anticoagulants prior to, during, or immediately following dental or surgical procedures, it is recommended that the dosage of COUMADIN (crystalline warfarin sodium) be adjusted to maintain the prothrombin time at approximately 1½ to 2½ times the control level. The operative site should be sufficiently limited to permit the effective use of local procedures for hemostasis including absorbable hemostatic agents, sutures, and pressure dressings if necessary. Under these conditions dental and surgical procedures may be performed without undue risk of hemorrhage.

COUMADIN with Heparin—Since a delay intervenes between the administration of the initial dose and the therapeutic prolongation of prothrombin time, it may be advisable in emergency situations to administer sodium heparin initially along with COUMADIN. The initial dose of heparin and injectable COUMADIN may be administered together in the same syringe.

It should be noted that heparin may affect the prothrombin time, and therefore, when patients are receiving both heparin and COUMADIN, the blood sample for prothrombin time determination should be drawn just prior to the next heparin dosage, at least 5 hours after the last intravenous injection or 24 hours after the last subcutaneous injection.

TREATMENT FOR OVERDOSAGE Excessive prothrombinopenia, with or without bleeding, is readily controlled by discontinuing COUMADIN (crystalline warfarin sodium), and if necessary, the oral or parenteral administration of vitamin K_1. The appearance of microscopic hematuria, excessive menstrual bleeding, melena, petechiae or oozing from nicks made while shaving are early manifestations of hypoprothrombinemia beyond a safe and satisfactory level.

In excessive prothrombinopenia with mild or no bleeding, omission of one or more doses of COUMADIN may suffice; and if necessary, small doses of vitamin K_1 orally, 2.5 to 10 mg, will usually correct the problem.

If minor bleeding persists, or progresses to frank bleeding, vitamin K_1 in doses of 5 to 25 mg may be given parenterally. (Please note recommendations accompanying vitamin K preparations prior to use.)

Fresh whole blood transfusions should be considered in cases of severe bleeding or prothrombinopenic states unresponsive to vitamin K_1.

Resumption of COUMADIN administration reverses the effect of vitamin K_1, and a therapeutic hypoprothrombinemia level can again be obtained.

SUPPLIED Tablets: COUMADIN (crystalline warfarin sodium, USP). For oral use, single scored, imprinted numerically with potency as follows: 2 mg lavender, 2½ mg orange, 5 mg peach, 7½ mg yellow, 10 mg white. In bottles of 100 and 1000. Also available in Hospital Unit-Dose blister package of 100.

Injection: Available as single injection units of amorphous warfarin sodium lyophilized for intravenous or intramuscular use in a box of 6 units for use immediately after reconstitution.

50 mg: Unit consists of 1 vial, 50 mg; sodium chloride, 10 mg; thimerosal, 0.2 mg. pH is adjusted with sodium hydroxide, accompanied by a 2 ml ampul Sterile Water for Injection.

Sterile Water for Injection contains no antimicrobial or other substance, and it is not suitable for intravascular injection without first having been made approximately isotonic by the addition of a suitable solute. Use only for reconstitution of the lyophilized product.

Injection manufactured by Lypho-Med, Inc., Chicago, Illinois 60651 for Endo Laboratories, Inc.

DUPONT

97.5% HOLTER DETECTION ACCURACY

HOLTER II/AUTOSCAN

The Accuracy

Holter II/Autoscan is the ONLY Holter System that computer analyzes every ECG complex on a "real time", beat-by-beat basis, DURING the actual patient monitoring period. Every ECG complex is compared to that patient's averaged updated "normal" complex for changes in rate, rhythm, morphology and signal quality (artifact). Since this computer analysis is performed at "real-time" rather than 60, 120, 240, or 480 times normal, Holter II/Autoscan has achieved a level of detection accuracy and ease of operation not possible with any other Holter system. Clinical Studies* have demonstrated an average of 97.5% quantitative detection accuracy and 100% qualitative detection accuracy. And, since the tape you receive from the patient is completely "pre-analyzed", only 6 minutes of operator time is required to process the tape.

The Challenge

Holter manufacturers' advertising often contains cla of increased accuracy of their respective syste However, data to support these claims are rarely, if e provided. Now IMC has taken the lead with the validated Holter system on the market.

WE CHALLENGE YOU TO COMPARE HOLTER II/AUTOSCAN:

- **TO YOUR PRESENT HOLTER SYSTEM**
- **TO ANY HOLTER SYSTEM YOU ARE CONSIDERING FOR PURCHASE**

If you want to know what you have been (or will missing; stop by IMC's booth at the ACC Meetin check the system you want to compare on this ad send it along with your name and address to IMC, (or our toll free phone number). We will provide y patient Holter tape compatible with the system yo dicate, a hand count of every abnormal complex c ified by type of anomaly, and the detection accura the Holter II/Autoscan System for that tape. We k you'll find the results to be enlightening!

Update on Oral Anticoagulation

TREATING MYOCARDIAL INFARCTION AND REDUCING THE THREAT OF THROMBOEMBOLISM

Each year in this country approximately one million people suffer acute myocardial infarctions. Rapid emergency treatment in coronary care units has been credited with reducing by up to one third the mortality among patients hospitalized with acute attacks.[1]

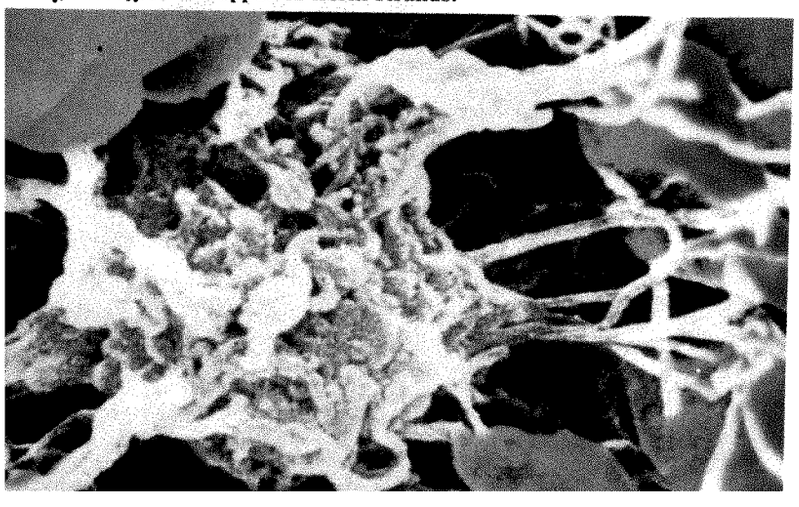
Thrombosis—incidence in myocardial infarction Following the damage to the heart itself, thromboembolism is perhaps the most serious sequel to myocardial infarction.

A study has demonstrated that there is a 39% incidence of calf vein thrombosis during the acute phase of myocardial infarction.[1]

Speed saves lives It has been reported that more than half the thrombi destined to occur in the calf veins form within 72 hours of myocardial infarction, and three-fourths form within the first week. Therefore, a number of investigators have recommended that antithrombotic measures should begin upon admission to the hospital and be effective almost immediately.[2]

Oral anticoagulants have a clinical value It has also been stated that the use of anticoagulants may reduce the frequency of calf vein thrombosis from 22 to 6.5%. The use of anticoagulants is subject to differing opinions regarding improved survival. A number of authorities recommend the use of anticoagulants in *all* patients who have no specific contraindications during the period of hospitalization.[1]

Scanning electron micrograph of 'Red' thrombus, formed by erythrocytes entrapped in fibrin strands.



One team of investigators in M.I. recommends providing full-dose warfarin while the patient is in the hospital and for several days afterward—

if the patient has had prior infarcts or thromboembolism
if the area of infarction is large
if complications (such as CHF or hypotension require prolonged bed rest.

But, if post myocardial infarction syndrome (Dressler's syndrome) develops, anticoagulants should be discontinued, as pericardial hemorrhage even cardiac tamponade may develop.[1]

Objectives and benefits of anticoagulation The use of anticoagulants in the acute phase of myocardial infarction has these potential advantages:[2]

prevention of deep vein thrombosis
reduction of embolization from cardiac mural thrombi
prophylaxis against extension of myocardial necrosis or long-term recurrence of infarction
reduction of overall mortality

If anticoagulants can inhibit the formation of deep vein thrombi, then the incidence of pulmonary embolism might be diminished—and pulmonary embolism has been estimated as a threat to life in 5,000 of the 500,000 myocardial infarction patients who are admitted to hospitals in this country each year.

A look at survival One retrospective study of the use of anticoagulants in M.I. evaluated the survival of 1,307 patients from 20 hospitals in a large metropolitan community. The diagnosis of M.I. was based on predefined criteria, which included typical chest pain, serial ECG's, enzyme elevations, and autopsy findings.

Among anticoagulated patients, the adjusted in-hospital case-fatality rate was 18%. For patients who did not receive this treatment, the fatality rate was 31%. For survivors followed for as long as ten years, patients who had been anticoagulated still fared better than those not so treated.[3]

Dedicated to Cardiovascular Support Instrumentation

Here is *the* list of books you'll need to update your library . . .

ECHOCARDIOGRAPHY, 3rd ed.

By HARVEY FEIGENBAUM, M.D., *Indiana University School of Medicine, Indianapolis.* This book by Doctor Harvey Feigenbaum has been the principle authoritative book in the field since publication of the first edition. This new Third Edition maintains and improves on that status. It represents a definitive, thorough discussion of instrumentation, technical aspects of application, and future trends by a pioneer in the field. Major coverage of two-dimensional echocardiography is featured. Discussion of this relatively new technique represents a major part of the text and is the principle reason for the increase in size. It is now completely reorganized to reflect current change in the status of echocardiography as an integral part of clinical cardiology. Several hundred new illustrations add to the usefulness of the book, and permit it to function as an atlas. The extensive list of up to date references enhance its value as a superior reference source. *580 pp. (7 × 10), 732 illus. (2 in color), 1981, $35.00.*

AMBULATORY ELECTROCARDIOGRAPHY: Including Holter Recording Technology

By HAROLD L. KENNEDY, M.D., *Johns Hopkins Hospital and the University of Maryland, Baltimore, Maryland.* This long-needed monograph describes the state of the art of ambulatory electrocardiography and Holter technology, and serves as a textbook with regards to its technique, interpretation and clinical indications. The content is directed specifically to both physicians and cardiovascular technical personnel interested in performing and interpreting ambulatory electrocardiographic examinations. Doctor Kennedy is well aware of emerging Holter technologies which show promise of becoming important in the future, and has made every effort to produce a very up-to-the-minute book for a rapidly changing field. No other book deals so completely and comprehensively with the practical aspects of this technology, its data analysis and interpretation, and the ambulatory electrocardiography literature. *About 300 pp. (7¼ × 10¼), 204 illus., 5 tables, 1981, Ready Soon.*

CARDIAC CATHETERIZATION AND ANGIOGRAPHY, 2nd ed.

Edited and with contributions by WILLIAM GROSSMAN, M.D., *Peter Bent Brigham Hospital, Boston, Massachusetts.* (*24 Contributors*). Taking a highly pragmatic approach, this new edition provides a completely up-to-date summary of the major techniques currently employed in cardiac catheterization and angiography. Review of previous edition: "Magnificent . . . the best current book on cardiac catheterization."—*The American Journal of Cardiology. 427 pp. (7 × 10), illus., 1980, $34.50.*

Plan now to examine our many new books at the American College of Cardiology meeting in San Francisco, California, March 16–19, 1981. We will be at Booth 2121.

CARDIAC REHABILITATION, ADULT FITNESS, AND EXERCISE TESTING

By PHILIP K. WILSON, Ed.D., *La Crosse Exercise Program, University of Wisconsin, La Crosse;* PAUL S. FARDY, Ph.D., *St. Catherine Hospital, East Chicago, Indiana; and* VICTOR F. FROELICHER, M.D., *University of California, San Diego.* This book provides extensive coverage of all aspects of cardiac rehabilitation and adult fitness programs, with additional emphasis placed upon theory, procedures, and techniques of exercise testing. *462 pp., illus., 1981, $29.50.*

PROGRESS IN CARDIOLOGY. 9

Edited by PAUL N. YU, M.D., *University of Rochester School of Medicine and Dentistry, Rochester, New York; and* JOHN F. GOODWIN, M.D., *Royal Postgraduate Medical School, London, England.* (*22 Contributors*). Chapters discuss management of the late phase of acute myocardial infarction; detection of postinfarction ventricular aneurysm using cross-sectional echocardiography and radionuclide ventriculography; the current status of computed tomographic (CT) scanning of the heart; etc. *193 pp. (7 × 10), illus., 1980, $15.00.*

GUIDELINES FOR GRADED EXERCISE TESTING AND EXERCISE PRESCRIPTION, 2nd ed.

Edited by the AMERICAN COLLEGE OF SPORTS MEDICINE, *Madison, Wisconsin. Prepared by the Preventive and Rehabilitative Programs Committee.* The new Second Edition sets forth a rationale for the establishment of effective graded exercise testing, exercise prescription, and exercise programs for asymptomatic subjects, as well as patients with cardiovascular and respiratory disease. *151 pp., tables, paperback, 1980, $6.50.*

CARDIAC EMERGENCY CARE, 2nd ed.

Edited and with contributions by EDWARD K. CHUNG, M.D., *Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania.* (*22 Contributors*). Busy physicians will appreciate the new format and quick and easy access to information provided in this Second Edition. Three new chapters dealing with sick sinus syndrome and brady-tachyarrhythmia syndrome, nursing aspects of cardiac emergency care, and radiological diagnosis in cardiopulmonary emergencies are included. *475 pp., illus., tables, 1980, $25.00.*

KAON CL™-10
(potassium chloride)
10 mEq Controlled Release Tablets

Easy-to-remember b.i.d. dosage

Just one KAON CL™-10 wax-matrix tablet b.i.d. supplies 20 mEq KCl. Two tablets b.i.d. supply 40 mEq KCl.

Easy to comply

B.i.d. instead of conventional t.i.d. dosage makes it easier for your patients to follow your instructions...increases likelihood of full compliance.

Easy to take, easy to carry

KAON CL-10 tablets have no taste or aftertaste...can be easily carried anywhere.

Easy dosage adjustment

Dosage may be individually adjusted, based on logical, easy-to-determine multiples of 10.

Easy on the purse

KAON CL-10 tablets offer your patients greater economy because fewer tablets deliver the same amount of potassium at a lower cost.

Easy on the GI tract

Special wax-matrix delivery system permits gradual release of KCl over several hours to minimize high localized concentrations in the GI tract, thus minimizing the chance of GI irritation. The frequency of small bowel lesions with wax-matrix tablets is less than one per 100,000 patient years.

for patients who can't or won't take liquid supplements

Brief Summary

Description: Kaon Cl™-10 mEq is a sugar coated (not enteric-coated) tablet containing 750 mg potassium chloride (equivalent to 10 mEq potassium chloride) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

Indications: BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUIDS OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.

1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis, in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For the prevention of potassium depletion when the dietary intake is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites, states of aldosterone excess with normal renal function, potassium-losing nephropathy, and with certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

Contraindications: Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: Chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (e.g., spironolactone, triamterene).

Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to enlarged left atrium. Potassium supplementation, when indicated in such patients, should be with a liquid preparation.

All solid dosage forms of potassium chloride supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

Warnings: Hyperkalemia—In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic. The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.

Interaction with Potassium Sparing Diuretics—Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (e.g., spironolactone or triamterene) since the simultaneous administration of these agents can produce severe hyperkalemia.

Gastrointestinal Lesions—Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Kaon Cl™-10 mEq (potassium chloride) is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains less than one per 100,000 patient years. Kaon Cl-10 mEq should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.

Metabolic Acidosis—Hypokalemia in patients with metabolic acidosis should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, potassium acetate, or potassium gluconate.

Precautions: The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis per se can produce hypokalemia in the absence of a deficit in total body potassium while acute acidosis per se can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

Adverse Reactions: The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.

The most severe adverse effects are hyperkalemia (see Contraindications, Warnings and Overdosage) and gastrointestinal obstruction, bleeding or perforation (see Warnings).

Overdosage: The administration of oral potassium salts to persons with normal excretory mechanisms for potassium rarely causes serious hyperkalemia. However, if excretory mechanisms are impaired or if potassium is administered too rapidly intravenously, potentially fatal hyperkalemia can result (see Contraindications and Warnings). It is important to recognize that hyperkalemia is usually asymptomatic and may be manifested only by an increased serum potassium concentration and characteristic electrocardiographic changes (peaking of T-waves, loss of P-wave, depression of S-T segment, and prolongation of the QT interval). Late manifestations include muscle-paralysis and cardiovascular collapse from cardiac arrest.

Treatment measures for hyperkalemia include the following:

1. Elimination of foods and medications containing potassium and of potassium-sparing diuretics.
2. Intravenous administration of 300 to 500 ml/hr of 10% dextrose solution containing 10-15 units of crystalline insulin per 1,000 ml.
3. Correction of acidosis, if present, with intravenous sodium bicarbonate.
4. Use of exchange resins, hemodialysis, or peritoneal dialysis.

In treating hyperkalemia, it should be recalled that in patients who have been stabilized on digitalis, too rapid a lowering of the serum potassium concentration can produce digitalis toxicity.

Caution: Federal law prohibits dispensing without prescription.

How Supplied: Bottles of 100 and 500; Stat-Pak® (Unit-Dose) box of 100.

CLINICAL STUDIES

Left Ventricular Function in Chronic Aortic Regurgitation With Reference to End-Systolic Pressure, Volume and Stress Relations

MARY OSBAKKEN, MD, PhD*
ALFRED A. BOVE, MD, PhD, FACC†
JAMES F. SPANN, MD, FACC

Philadelphia, Pennsylvania

Left ventricular muscle and pump performance were evaluated in 12 normal subjects and 21 patients with aortic regurgitation (10 with minimal symptoms and 11 with congestive heart failure). A computer-based quantitative analysis of biplane left ventriculograms was used. Both patient groups had significant aortic regurgitation documented by ventriculography. Contractile function measured by peak systolic stress/end-diastolic volume and end-systolic pressure/volume curves was poorer than that in normal subjects in patients with heart failure but not in asymptomatic patients. When normalized for muscle mass, stroke work was not depressed in either asymptomatic patients (mean ± standard error of the mean 0.008 ± 0.001 joules/g) or patients with heart failure (0.009 ± 0.004) by comparison with the value in normal subjects (0.010 ± 0.001).

Angiographically determined cardiac index (CI) increased with increasing volume overload even though forward cardiac index measured by the Fick method remained essentially unchanged: normal subjects (total CI 3.7 ± 0.4 liters/min per m^2, Fick CI 2.4 ± 0.1); asymptomatic patients (total CI 7.6 ± 0.7, Fick CI 2.3 ± 0.2); patients with heart failure (total CI 9.1 ± 0.82, Fick CI 2.1 ± 0.18). Left ventricular peak stress increased significantly in patients with heart failure (511 ± 55 dynes/cm^2 × 10^{-3}) compared with values in normal subjects (360 ± 33) and asymptomatic patients (428 ± 50).

The combination of decreased muscle function and increased demands on pump function causes a significant increase in end-diastolic pressure only in patients with heart failure (23 ± 2 mm Hg), which results in pulmonary congestive symptoms.

Debate continues about left ventricular contractile performance in volume overload caused by aortic regurgitation.[1–10] Depending on the definitions and measures of contractility used, various authors maintain that contractility is increased,[1] normal[2–5] or decreased.[1–3] Commonly used isovolumic phase indexes may be distorted in severe aortic regurgitation because the isovolumic phase of the cardiac cycle is shortened, but the classic Frank-Starling curve, relating performance to end-diastolic length, may be more reliable. Sagawa et al.[11–13] defined a new measure of contractility based on the relation of end-systolic pressure

to end-systolic volume. This method is only minimally influenced by preload and afterload and is suitable for evaluation of ventricular performance in volume overload states. We studied left ventricular contractile and pump function in chronic aortic regurgitation, using conventional methods such as stroke work index, ejection fraction and the Frank-Starling relation, as well as the new measure of contractility developed by Sagawa et al.[11]

Methods

Patient selection: Thirty-three subjects were studied: 12 normal subjects and 21 patients with aortic regurgitation (10 who were relatively asymptomatic and 11 who had congestive heart failure).

All 12 normal subjects were studied because of a chest pain syndrome. All 12 had angiographically normal coronary arteries, normal regional wall motion and no evidence of valve or shunt lesions. Their left ventricular end-diastolic pressure was 12 mm Hg or less and their ejection fraction was greater than 50 percent. Their mean age was 46 years (range 20 to 69). There were six men and six women.

Ten patients with significant angiographically judged aortic regurgitation who had only minimal symptoms (New York Heart Association[14] functional classes I and II) were selected for the asymptomatic group. None of these patients had coronary disease or mixed valve lesions. Six had chest pain and five had dyspnea on extreme exertion, but none limited activity because of such symptoms. The mean age of this group was 45 years (range 20 to 71). There were five men and five women.

Eleven patients with angiographic evidence of significant aortic regurgitation associated with symptoms of heart failure at rest or on performing minimal activity (functional classes III and IV) were selected for the group with heart failure. None of these patients had angiographic evidence of coronary artery disease or mixed valve lesions. Four patients had chest pain, 10 had paroxysmal nocturnal dyspnea, 4 had peripheral edema, 2 had syncope and all 11 had dyspnea at rest or on minimal exertion. The mean age of this group was 51 years (range 20 to 71). There were 3 women and 8 men.

Cardiac catheterization: All 33 subjects underwent cardiac catheterization in the fasting state with mild sedation and local anesthesia; either the femoral or the brachial arterial technique was used.[15,16] Aortic and left ventricular pressure measurements were made with dual Millar micromanometer catheters in 15 patients and with fluid-filled catheters connected to Statham (P23Db) pressure transducers in the remaining 18.

Left ventricular pressure was recorded just before angiography with the fluid-filled catheters, and simultaneously with the left ventriculogram when the micromanometer catheter was used. The nonsimultaneous pressure recordings were traced on a digital plotting table and synchronized with the ventriculographic data using the R wave of the electrocardiogram as a reference. We tested the time difference between the micromanometer and fluid-coupled pressure waves measured with similar catheters in two dogs. The peak left ventricular pressure of the fluid-coupled waveform lagged behind the peak of the micromanometer waveform by 13.2 ± 3.1 ms (mean ± standard error of the mean), a lag of less than one cine frame. This delay is not large enough to affect the end-systolic pressure measurement. We have used this method in a previous study and found no difference between the data obtained from the two catheters.[17]

Cardiac output was determined by the Fick method or by cardiogreen indicator dilution curves.

Ventriculographic recording: Monoplane (5 patients) and biplane (28 patients) 35 mm cineventriculograms of the left ventricle were exposed at 60 frames/s. Contrast medium was injected at a rate of 11 to 15 ml/s for 3 seconds. The electrocardiogram and pressure tracings were recorded simultaneously on the cine film with the ventriculogram or on a continuous recorder at a rate of 50 mm/s. A timed light pulse was recorded on the biplane films to provide precise synchronization between the two films during analysis. The monoplane studies were performed in the 30° right anterior oblique position. The biplane studies were performed in both the 30° right and 60° left anterior oblique positions.

Ventriculographic data analysis: Pressure, volume and electrocardiographic data were digitized, frame by frame, using a digital plotting table. To minimize the effects of contrast medium, the earliest well opacified beat was analyzed. For each patient, the left ventricular outline was digitized for 60 to 80 frames representing 1.5 cardiac cycles.[18] Premature ventricular complexes and postpremature ventricular complexes were not analyzed. Left ventricular volume was calculated using the formula of Rackley et al.[19] Stroke work and wall stress were calculated using methods we[18] have previously described in detail.

Statistical analysis: One way analysis of variance was used to compare data from the three groups. Linear regression analysis was performed on the contractile function data.

Results

Hemodynamic data (Table I): Hemodynamic data are presented in Table I. Compared with values in the normal group, mean aortic pressure, left ventricular end-systolic pressure and left ventricular end-diastolic presssure were increased significantly only in the group with heart failure. End-diastolic volume index was increased significantly in both the asymptomatic patients and those with heart failure, but end-systolic volume

index was increased significantly only in the group with heart failure. Stroke volume index was increased significantly from the value in the normal group in both groups of patients with aortic regurgitation. However, ejection fraction was significantly decreased only in the group with heart failure.

The total cardiac index measured angiographically increased with progressive volume overload, but forward cardiac index measured with either Fick or dye-dilution methods did not increase, indicating that a significant proportion of cardiac work was expended on regurgitant volume.

Data on ventricular hypertrophy and work (Table II). Chronic volume overload produced significant myocardial hypertrophy, evidenced by an increase in left ventricular mass index, in both the asymptomatic patients and the group with heart failure. Although the ratio of left ventricular mass to end-diastolic volume was not statistically different among the groups, this ratio was somewhat higher in the asymptomatic group. Wall thickness (h) and minor axis radius (R) were measured at one-half the distance between the aortic valve and apex. The ratio (h/R) was significantly higher than normal in the asymptomatic group. The data on these two indexes suggest that hypertrophy per unit of volume overload was greater in the asymptomatic group than in the group with heart failure.

Stroke work index increased with increased volume overload, whereas stroke work per gram of heart muscle did not. This finding indicates that muscle hypertrophy compensated for excess stroke work and maintained work constant per muscle unit.

Wall stress (Table III): Compared with the value in the normal group, peak wall stress increased by 19 percent in the asymptomatic group and by 42 percent in the group with heart failure, and end-systolic stress increased by 13 and 46 percent, respectively, in two patient groups.

Similarly, compared with the value in the normal group, end-diastolic stress almost doubled in the group with heart failure, but did not increase in the asymptomatic group. From these data, it appears that peak end-systolic and end-diastolic stresses were somewhat normalized by hypertrophy only in the asymptomatic group.

Contractile performance: Left ventricular contractile performance was measured by the Frank-Starling relation and with two Sagawa elastance curves. The Frank-Starling relation of peak systolic stress versus end-diastolic volume index is shown in Figure 1. Estimates of average ventricular function for each group were obtained from the naturally occurring variation in ventricular volume. The effects of wall thickness and

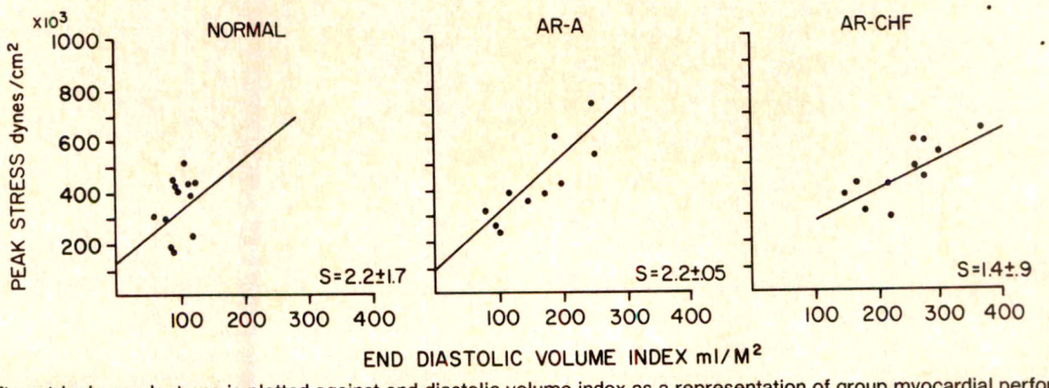

FIGURE 1. Left ventricular peak stress is plotted against end-diastolic volume index as a representation of group myocardial performance. Each point is obtained from one patient in the respective group. The **solid lines** are linear regression estimates of the individual data points. The slope (s) and the standard errors are listed for each group. The slope for the group with heart failure is lower than normal, but the difference is not significant. AR-A = aortic regurgitation, asymptomatic group; AR-CHF = aortic regurgitation, group with congestive heart failure.

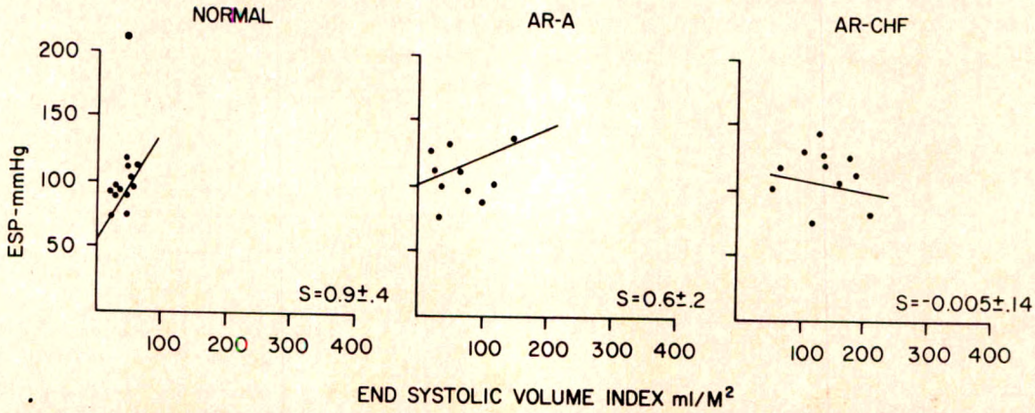

FIGURE 2. Group contractile function expressed by the relation of left ventricular end-systolic pressure (ESP) to end-systolic volume index. Each point is obtained from an individual patient. The **solid lines** are linear regression estimates of individual data points. The slopes and the standard errors are listed for each group. The slope of the group with heart failure is significantly ($p < 0.05$) lower than normal. Abbreviations as in Figure 1.

left ventricular pressure were accounted for by measuring systolic wall stress. The slope of the linear regression for this index was depressed for the group with heart failure in comparison with the other two groups.

The first Sagawa curve[11–13] utilizes the relation between end-systolic pressure and end-systolic volume to describe ventricular performance. The slope of this relation (Emax) is an index of contractility that is minimally influenced by changes in afterload or preload. The naturally occurring variations in end-systolic volume among patients in each group can be used to construct linear regression estimates of the average Emax line (Fig. 2). The slope of this curve was depressed in the group with heart failure, indicating that contractility was decreased in this group. The second Sagawa curve accounts for variations in wall thickness, left ventricular pressure and volume by plotting end-systolic stress against end-systolic volume index (Fig. 3). The slope for the group with heart failure was significantly depressed and the slope for the asymptomatic group was also below normal but not to a statistically significant extent.

With use of the same data, end-systolic pressure/volume and end-systolic stress/volume ratios were calculated for each patient (Table I). Both ratios were significantly decreased in the group with heart failure but not in the asymptomatic group.

Discussion

Our analysis of left ventricular performance in aortic regurgitation indicates that contractile and pump functions are reduced when the chronic volume overload progresses to congestive heart failure, but contractile function appears normal and pump function is not significantly reduced in patients whose chronic volume overload has not yet progressed to congestive heart failure.

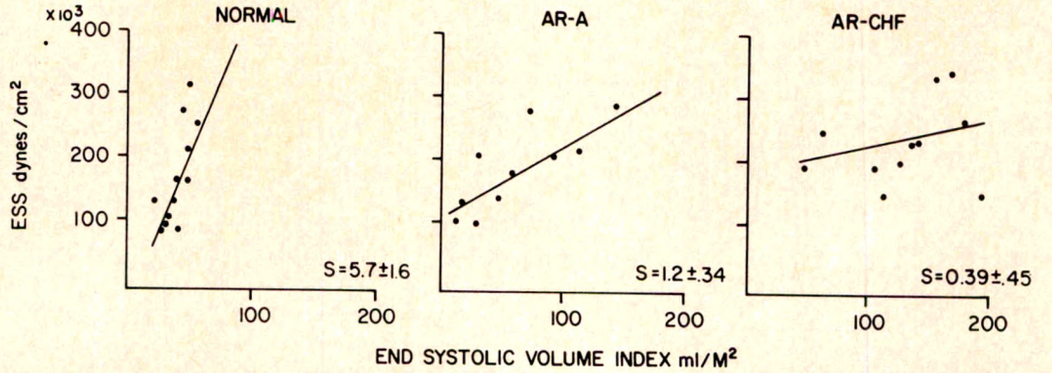

FIGURE 3. Left ventricular end-systolic stress (ESS) plotted against end-systolic volume index as a representation of group myocardial performance. Each point is obtained from one patient in the respective group. The **solid lines** are linear regression estimates of the individual data points. The slopes and the standard errors are listed for each group. The slope of the group with heart failure is significantly ($p < 0.05$) lower than normal. Abbreviations as in Figure 1.

Data on hemodynamics and hypertrophy: Progressive volume overload in our patients with aortic regurgitation produced progressive increases in end-diastolic volume, end-systolic volume and stroke volume. As aortic regurgitation became more severe, stroke volume increased to a level much higher than normal, but end-diastolic volume increased to an even greater degree. Thus, ejection fraction decreased as aortic regurgitation became more severe. These changes suggest that a Frank-Starling type of compensation occurs initially in volume overload, but as the volume overload becomes more severe, the left ventricle is unable to compensate for the overload, pump function begins to fail and congestive heart failure ensues.

Total cardiac index measured angiographically increased with increasing volume overload, but forward cardiac index measured with either the Fick or the dye-dilution method did not increase. Therefore, a significantly greater regurgitant volume accounted for the increase in total cardiac output, but this regurgitant volume was essentially ineffective flow and did not contribute to the metabolic needs of the patient. Nevertheless, considerable myocardial energy is expended to maintain this regurgitant volume, and the heart's ability to function without failing under these conditions indicates that Frank-Starling compensation is effective in asymptomatic patients. However, among patients with heart failure, our data show that decompensation has occurred. This decompensation may be the result of volume overload that is too large for the ventricle to pump effectively, but our data suggest that it is due to reduced contractile performance of the myocardium.

Hypertrophy, measured by mass index and wall thickness, increased with increasing volume overload, and the ratios of mass to end-diastolic volume and wall thickness to minor axis were above normal only in the asymptomatic group. These findings, consistent with those of other investigators,[1,2,6] suggest that there was appropriate hypertrophy in both the symptomatic patients and those with heart failure, although there may be excess hypertrophy in the asymptomatic group. The patients with heart failure had increased wall stress in both systole and diastole, suggesting that further hypertrophy would have been necessary to normalize stress for this group, a finding that is also consistent with the data of other investigators.[3,8,20,21] The asymptomatic group had normal or near normal wall stress in both systole and diastole.

Contractile characteristics: Several measurements have been used to evalute myocardial contractility in volume overload states. Mehmel et al.[1] used the left ventricular pressure derivative, contractile element velocity of shortening and velocity of peak shortening and found that both pressure derivative and shortening velocity were increased in aortic regurgitation while velocity at peak shortening was decreased. Miller et al.[5] used pressure derivative and stroke work/end-diastolic volume ratio and found that patients with a very high end-diastolic volume had a decreased ejection fraction, decreased pressure derivative and decreased stroke work/end-diastolic volume ratio. Other investigators have used exercise, atrial pacing, afterload augmentation with angiotensin, and afterload reduction with nitroprusside to study contractile function in aortic regurgitation.

In patients without heart failure Levinson et al.[6] showed that exercise increased forward flow while decreasing systolic ejection period, peripheral vascular resistance, regurgitant flow and tension-time index, without changing total work. Judge et al.[21] used atrial pacing to vary the heart rate in patients with aortic regurgitation and demonstrated that increased heart rate resulted in decreased end-diastolic pressure, decreased stroke volume, decreased end-diastolic stress, and increased forward cardiac output. In both studies, the extent of these responses was reduced in patients with congestive heart failure. Bolen et al.[2] used afterload augmentation with angiotensin to determine whether a patient's left ventricular function should be classified as compensated or decompensated. Patients who were able to maintain an ejection fraction greater than 50 percent were classified as having compensated myocardial function, whereas those whose ejection fraction fell below 50 percent were classified as having decompensated function. In another study, Bolen and Alderman[10] used afterload reduction with nitroprusside to study left ventricular function and found that the best response to this intervention was from patients with decreased ejection fraction and cardiac output and with increased end-diastolic and mean aortic pressures.

The data from our study suggest that contractile function is decreased in severe aortic regurgitation when evidence of left ventricular failure is found clinically. However, this finding should be interpreted cautiously because changes in afterload and preload may affect the validity of the indices we used to evaluate contractile function. Table I shows that mean aortic and left ventricular systolic pressures were elevated in both groups of patients with aortic regurgitation, indicating that afterload as well as preload was altered in these patients. We used several measures of contractile performance to account for or to avoid these effects. The Frank-Starling relation of peak stress versus end-diastolic volume index accounts for preload by incorporating preload into the index while use of stress as the performance index accounts for the increased wall thickness encountered in aortic regurgitation. The relation between end-systolic pressure and end-systolic volume has also been used as an index of contractile performance.[23,24] This relation, described by Sagawa et al.[11–13] is thought to be independent of preload and afterload. To account for the wall thickness variations in the Sagawa index, we used end-systolic stress as well as end-systolic pressure to determine the contractile state of the ventricle. Although the Frank-Starling relation suggested decreased performance, the two Sagawa type relations clearly indicate that ventricular function is depressed in severe aortic regurgitation when heart failure is evident clinically.

Possible limitations of method: Although the three performance curves we used provide useful information

on ventricular performance, there are some limitations to this technique. To compare the three groups, we assumed that the normal curves are linear over the range of volumes measured in all three groups. This assumption allowed us to compare the two groups of patients with aortic regurgitation with the normal group by assuming they functioned on a different curve of contractility when the slopes were different. In addition, we used the natural variation in end-diastolic and end-systolic volume among the patients to calculate the linear regression estimates of the data. The slopes were compared statistically to eliminate observer bias. In addition to these indexes, the ejection fraction was measured and found to be reduced only in the patients with aortic regurgitation who had heart failure.

Clinical implications: Our data indicate that hypertrophy alone does not result in decreased myocardial performance. There appears to be a degree of volume overload and of hypertrophy related with normal function; however, severe overload with further hypertrophy results in decreased myocardial performance and clinical evidence of congestive heart failure. In both states, the degree of hypertrophy is appropriate for the overload, but in the severe overload state, muscle performance is reduced and the ventricle fails.

Although we were unable to follow up these patients longitudinally, the data suggest that patients with aortic regurgitation progress to a symptomatic state when the regurgitant volume becomes greater and the end-diastolic volume and pressure increase. In association with these changes, the systolic myocardial stress increases, the degree of hypertrophy relative to end-diastolic size returns to normal and the ejection fraction decreases. Some of these changes can be detected by noninvasive measurement of left ventricular dimensions. Longitudinal evaluation of left ventricular dimensions and performance using noninvasive techniques may provide useful information regarding the need for surgical correction of the valve lesion in chronic aortic regurgitation.

Coronary Sinus Blood Flow at Rest and During Isometric Exercise In Patients With Aortic Valve Disease

Mechanism of Angina Pectoris in Presence of Normal Coronary Arteries

In 46 patients with aortic valve disease, coronary sinus blood flow wa measured using a continuous thermodilution method both at rest an during isometric handgrip excercise. All patients had normal coronar angiograms. The patients were separated into three groups: Group I, 1 patients with aortic stenosis (systolic gradient 72 ± 12 mm Hg); Grou II, 15 patients with both aortic stenosis and regurgitation; Group III, 1 patients with aortic regurgitation. At rest, the coronary sinus blood flo was two to three times normal. However, when corrected for left ven tricular mass (ml/100 g), flow was within normal limits. The ratio diastoli pressure-time index/systolic pressure-time index (DPTI/SPTI) was de creased in all three groups at rest. During isometric exercise, coronar sinus blood flow increased significantly: by 60 percent in Group I, by 8 percent in Group II and by 118 percent in Group III. There was a significar reduction of the DPTI/SPTI ratio.

Of the 18 patients with angina on effort during the test, 7 were in Grou I, 6 in Group II and 5 in Group III. There were no differences in the coronar sinus blood flow between the patients with angina and those who wer pain-free, either at rest or during exercise. Angina pectoris does not appea to be caused by a failure of coronary blood flow to increase. There wa no discrepancy between myocardial demand, as measured by the pres sure-time index and coronary blood flow. However, the DPTI/SPTI rati was significantly lower during exercise in the patients with angina tha in those who were pain-free. Underperfusion of the subendocardial muscl seems to be a causative factor in the patients with angina.

Angina pectoris is a common symptom in patients with aortic valv disease. Coronary angiography has demonstrated a relation betwee angina and coronary artery disease. However, many patients with bo severe aortic valve disease and angina pectoris have normal corona arteries. Several mechanisms have been suggested to account for angi in such patients. The few previous studies of coronary blood flow patients with aortic valve disease have been inconclusive. Experiment work on anesthetized dogs[1,2] demonstrated a decrease in mean corona flow in the presence of marked aortic regurgitation, whereas oth studies[3–5] have demonstrated increased coronary blood flow as compar with normal dogs. Foltz et al.[3] demonstrated a reversal of the normal high ratio of diastolic/systolic coronary flow in the presence of acu aortic regurgitation in dogs. Clinical studies[6–8] demonstrated an i creased coronary flow in patients with aortic regurgitation. In view the diversity of opinion and in order to study the mechanism of angi pectoris, we attempted to reinvestigate this question.

Methods

Study patients: Sixty-one patients were studied; 15 of the 61 were exclud because they had coronary artery disease, and the remaining 46 were classifi into three groups: Group I, 12 patients with aortic stenosis; Group II, 15 patier

From the Division of Cardiology and Hemodynamics, University Hospital, Lille, France. Manuscript received January 21, 1980; revised manuscript received July 10, 1980; accepted August 14, 1980.

with aortic stenosis and regurgitation; and Group III, 19 patients with aortic regurgitation. Eighteen patients complained of angina during exercise. Of these, 7 were in Group I, 5 in Group II and 6 in Group III. Coronary sinus blood flow and myocardial oxygen uptake at rest in the 46 patients were compared with values obtained from a previous study[14] of 13 normal persons.

Hemodynamic measurements: Cardiac catheterization was performed at rest after intravenous premedication with 100 mg of chlorozepate. Pressures were measured using Statham P23dB transducers and were recorded using an Electronics for Medicine VR 12 recorder. Right-sided pressures were obtained using Cournand catheters and left-sided pressures using Brockenbrough catheters. In patients with aortic stenosis, a transseptal approach was adopted, the catheter crossing the atrial septum and mitral valve. In patients with aortic regurgitation, the left ventricle was approached in retrograde manner. In all patients the aortic pressure was measured using a pigtail catheter, positioned just above the aortic valve. Aortic and left ventricular pressures were measured simultaneously. Cardiac output was assessed by the Fick method. A special 7F thermistor catheter was introduced into the coronary sinus in order to determine the coronary sinus blood flow, as described by Ganz et al.,[9] using a continuous thermodilution method.

Measurements of coronary sinus blood flow: Two measurements of coronary sinus blood flow were made at rest in each patient. Blood samples were taken from the coronary sinus and the aorta to determine their oxygen contents, CvO_2 and CaO_2, respectively. Isometric exercise was performed, handgrip being maintained at 50 percent of the maximal effort. The patient was in each case asked to speak loudly throughout, in order to exclude any Valsalva effect. Between the 3rd and 5th minutes, blood samples were again withdrawn and simultaneous aortic and left ventricular pressure measurements repeated. The position of the catheter in the coronary sinus was ascertained by injection of contrast medium.

Angiographic measurements: Single plane left ventricular cineangiography was performed at rest in the 30° right anterior oblique position. End-diastolic and end-systolic left ventricular volumes were measured and the ejection fraction was calculated using Simpson's rule and with the aid of the Philips Grafomed computer system. Left ventricular mass was obtained as described by Kennedy et al.[10].

The aortic regurgitant fraction (RF) was obtained using the formula:

$$RF = SV_A - SV_F / SV_A \times 100.$$

where SV_A is the total stroke volume as determined with angiography and SV_F is the stroke volume obtained by dividing the cardiac output by heart rate. It is assumed that the heart rate at the time of cardiac output measurement was the same as that during left ventriculography.

Aortic valve area was calculated from Gorlin's formula. It was noted that the valve area would be underestimated when aortic incompetence was present. Peak systolic wall stress (T) was determined from Laplace's equation: T = P.r/2d where P = intraventricular wall thickness. The internal left ventricular radius was derived from volume measurement as follows: $r = \sqrt[3]{3.V/4\pi}$.

The diastolic pressure-time index (DPTI) and the systolic pressure-time index (SPTI) were derived from simultaneous aortic and left ventricular pressure recordings. The DPTI/SPTI ratio was calculated as described by Buckberg et al.[11–13] and represents the ratio myocardial oxygen supply/myocardial oxygen demand. Myocardial oxygen uptake ($M\dot{V}O_2$) was calculated using the equation: $M\dot{V}O_2 = CSBF \times (CaO_2 - CvO_2)$.

Selective coronary angiography was performed using the Judkins technique.

Analysis of paired data and statistical significance was performed using Student's paired *t* test and the HP 9815 computer program.

Coronary sinus blood flow, arteriovenous oxygen difference [$(A\text{-}V)O_2$] and myocardial oxygen uptake ($M\dot{V}O_2$) at rest in 13 normal subjects and 46 patients with aortic valve disease. **Broken lines** indicate normal range. AR = aortic regurgitation; AS = aortic stenosis; N = normal.

tricular end-diastolic pressure were similar in all three groups of patients. Left ventricular end-diastolic pressure was increased in these groups, but no patient manifested heart failure. The ejection fraction and cardiac index were within normal limits except in patients in Group II (aortic stenosis and regurgitation), whose cardiac index fell slightly. The systolic ejection gradient across the aortic valve was similar in Group I (aortic stenosis) and Group II (aortic regurgitation). The regurgitant fraction was not significantly different in Group II and Group III. There was a marked increase in left ventricular end-diastolic volume among patients in Group III, values being greater than in Group I.

Left ventricular mass and wall stress: The left ventricular mass was greater than normal, but there were no significant differences among the three groups. The mass/volume ratio was greater than normal in patients in Groups I and II, but was less than normal in patients in Group III. Myocardial thickness was less in Group III than in Groups I and II. There were no significant differences in peak systolic wall stress among the three groups.

Coronary sinus blood flow: Coronary flow was higher in patients with aortic valve disease than in normal subjects (Table II). Figure 1 shows that coronary sinus blood flow generally reached two to three time

ormal values. There were no significant differences mong the three groups of patients with aortic valve isease. The coronary arteriovenous oxygen difference as the same in patients with aortic valve disease as in ormal subjects. In view of the increased coronary blood ow in the patients with valve disease, this finding reects a significantly increased myocardial oxygen upake.

The apparent increase in the coronary flow can be rrected for left ventricular mass as flow per 100 g of ft ventricular myocardium. The flow per unit mass on is basis is not significantly higher than in normal ubjects. There was no correlation between coronary nus blood flow and ventricular function (as measured y cardiac index and ejection fraction) or between corary flow and peak systolic wall stress or the mass/olume ratio. The DPTI/SPTI ratio was decreased in e three groups and was lower than the critical value .7) initially assigned by Buckberg et al.[13] to patients assified in Groups I and II.

ndings During Isometric Exercise

The hemodynamic and coronary sinus blood flow anges during handgrip exercise are summarized in ables I and II. There were significant increases in heart te, peak left ventricular systolic pressure and left ntricular end-diastolic pressure ($p < 0.01$). There was change in the systolic pressure gradient across the rtic valve in patients in Groups I and II.

Coronary sinus blood flow was significantly increased <0.01) in the three groups: by 60 percent in Group by 88 percent in Group II and by 118 percent in Group .

The coronary arteriovenous oxygen difference was changed, but the myocardial oxygen uptake was inased in proportion to the increased coronary sinus blood flow. The DPTI/SPTI ratio decreased significantly ($p < 0.01$) to very low values (mean less than 0.5) (Fig. 2).

Comparison of patients with and without angina (Table III): Eighteen patients (seven in Group I, five in Group II and six in Group III) had angina on effort. In none of the three groups were there differences between patients with and without angina in left ventricular end-diastolic volume, left ventricular mass or ejection fraction. In Groups I and III, left ventricular peak systolic pressure was higher in patients with than in those without angina. In Group III, left ventricular end-diastolic pressure was greater in the patients with than in those without angina. Patients whose aortic stenosis was complicated by angina had a greater systolic pressure gradient across the valve than did other patients in the same group.

With the exception of patients with aortic regurgitation, no differences in values at rest for coronary sinus blood flow or the DPTI/SPTI ratio were found between the patients with and without angina. In the presence of aortic regurgitation, patients with angina had a lower DPTI/SPTI ratio. During isometric excercise, coronary flow was the same in the two groups, but the DPTI/SPTI ratio was lower in patients with than in those without angina (Fig. 3). Hence it appears that the DPTI/SPTI ratio was more reliable than coronary flow as an indicator of the presence of angina.

Discussion

Coronary blood flow at rest in aortic valve disease: Our results indicate that coronary sinus blood flow and myocardial oxygen uptake, in a group of patients with aortic valve disease, are significantly higher than in a control group of normal subjects. The apparent increase is a consequence of the greater left ventricular

CI = cardiac index (liters/min per m^2); EF = ejection fraction (%); LVEDP = left ventricular end-diastolic pressure (mmHg); LVEDV = left ventricular end-diastolic volume index (ml/m^2); LVM = left ventricular mass (g/m^2); LVP = left ventricular peak systolic pressure (mm Hg); PSWS = peak systolic wall stress (g/cm^2); SPG = systolic pressure gradient across the aortic valve (mm Hg).

mass, the coronary sinus blood flow per 100 g of left ventricular myocardium being within normal limits.

These results are consistent with those of previous investigations in which myocardial blood flow per unit mass was measured at rest. Rose et al.[8], using nitrous oxide, studied seven patients with aortic stenosis and four with aortic regurgitation. They found the flow per unit mass to be the same for these patients as for normal subjects. Other authors, using nitrous oxide,[15,16] iodoantipyrine-131,[17,18] argon,[19] and hydrogen,[20] reported significantly different values for patients with aortic stenosis and normal control subjects. However, Johnson et al.[21] found the myocardial blood flow per unit mass to be reduced in 10 patients with aortic stenosis. The difference between these results may be accounted for by differences in methods. Johnson et al. measured myocardial perfusion using radioactive xenon-131 and a multiple crystal scintillation camera. We used the continuous thermodilution method, which measures flow from all parts of the myocardium draining to the coronary sinus. Thus the thermodilution method measures flow in the left ventricle, which is particularly involved in aortic valve disease.

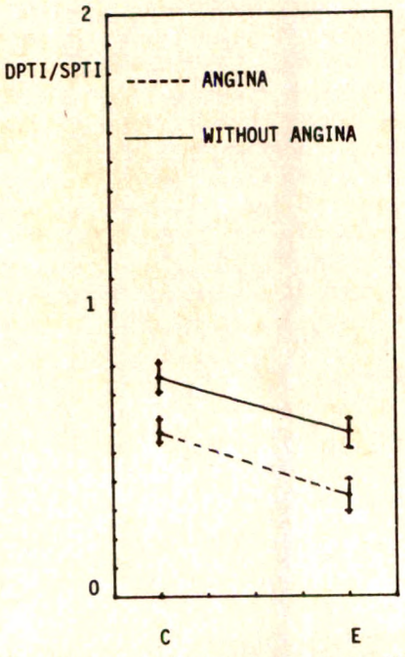

FIGURE 3. Comparison of DPTI/SPTI ratio in patients with and without angina pectoris; C = control; E = exercise.

Methodologic problems: At rest, the catheter was carefully positioned, there were no problems. During isometric excercise, shifts in catheter position can alter apparent flow by the inclusion or exclusion of some of the venous drainage vessels. In our study, the position of the catheter in the coronary sinus was carefully checked during the exercise test.

In 1978, Mathey et al.[22] demonstrated significant reflux of right atrial blood into the coronary sinus during ventricular pacing or rapid atrial pacing and during pulmonary arterial constriction. In view of this finding one might wonder whether the handgrip exercise test induces reflux into the coronary sinus. In order to exclude any Valsalva effect, each patient was asked to count in a loud voice. After the study was completed, a 7F Cournand catheter was introduced into the right atrium which was thereby injected with 10 ml of cold saline solution both at rest and during a second exercise test. In no case was there a change in coronary sinus blood temperature; hence, coronary sinus reflux was excluded as a source of error from our study.

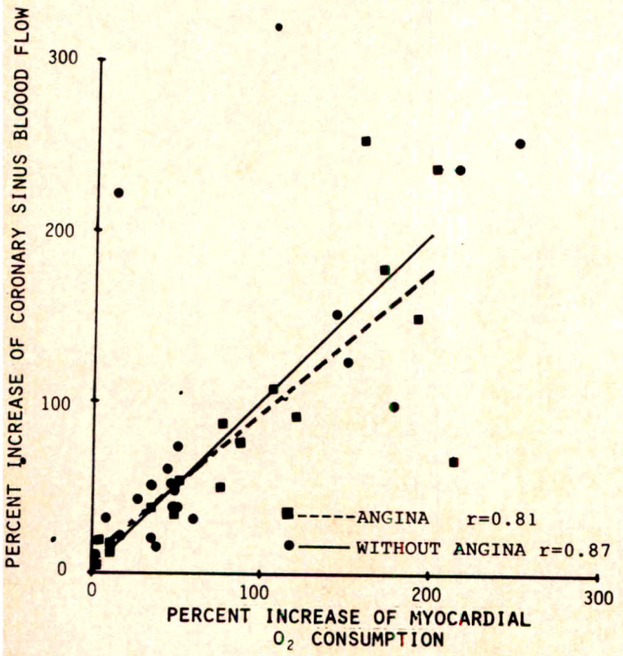

FIGURE 4. Relation between the myocardial oxygen supply (coronary sinus blood flow) and demand (myocardial O_2 consumption) in patients with and without angina.

Coronary blood flow during handgrip exercise n aortic valve disease: Handgrip exercise is not gen-rally thought to be a satisfactory stress test. In our tudy, handgrip exercise induced a slight but significant p <0.01) increase in heart rate, which reached 100 beats/min, as well as significant increases in left ven-ricular pressures. The pressure-rate product (left entricular peak systolic pressure × heart rate) rose ignificantly; by 53 percent in patients with aortic ste-osis and by 83 percent in patients with aortic regurgi-ation. There were significant increases in coronary inus blood flow; 60 percent in Group I, 88 percent in roup II and 118 percent in Group III.

To our knowledge, there have been few previous tudies of coronary blood flow during exercise in pa-ients with aortic valve disease. Rowe et al.[8] measured oronary blood flow during exercise performed on a icycle ergometer, but they induced a lesser tachycardia. hey found increases of 49 percent in patients with ortic stenosis and of 42 percent in those with aortic egurgitation. Although it has been reported that andgrip exercise is less valuable than dynamic exercise, andgrip testing is both simple and clinically conve-ient. Kivowitz et al.[23] measured a 46 percent increase n coronary sinus blood flow during a 5 minute handgrip xercise test during which 25 percent of the maximal oluntary contraction was maintained by seven patients ith coronary artery disease. At 30 percent of the aximal voluntary contraction, Katori et al.[24] observed n increased coronary sinus blood flow averaging 19.8 ercent in 21 patients with various diseases. In light of ese values, it appears that the usual response to this form of exercise was observed in our patients with aortic valve disease. It also appears that the reserve capacity of vasodilatation is unimpaired in these patients as is the ability of the heart to adjust its coronary flow by autoregulation in response to exercise.

Mechanism of angina pectoris in patients with aortic valve disease: The mechanism remains unclear. Fallen et al.[18] suggested that angina occurs because myocardial oxygen consumption exceeds the available supply. It is well known that three main factors determine myocardial oxygen consumption: heart rate, left ventricular wall tension and contractility. Various indexes of myocardial oxygen consumption have been calculated. The pressure-time index (product of heart rate and peak systolic pressure) is considered to reflect the myocardial oxygen requirement. Swanton et al.[25] observed that in patients with angina and aortic stenosis but normal coronary arteriograms, manifested significantly higher peak left ventricular pressure, peak systolic gradient and left ventricular end-diastolic pressure, and had a larger left ventricular mass than did a control group of normal subjects. In our study, there were no significant differences in the increases in coronary sinus blood flow and the pressure-time index between patients with or without angina, in any of the three groups (pure aortic stenosis, combined aortic stenosis and regurgitation, and pure aortic regurgitation).

We found that the regression lines for plots of coronary sinus blood flow and myocardial oxygen uptake were similar for patients with and without angina. (Fig. 4). This was also true of plots of coronary sinus blood flow and pressure-time index, demonstrating the validity of this indirect index. These results suggest that angina does not result from an imbalance in myocardial oxygen demand and supply.

The Venturi effect at the coronary ostia has been observed in both aortic stenosis and aortic regurgitation. It can impair or even reverse coronary flow during the cardiac cycle, thus changing the perfusion of the subendocardial layers. It has been previously demonstrated that subendocardial flow is determined by the interplay of the following factors: coronary arterial diastolic pressure, left ventricular intramural diastolic pressure and the duration of diastole. These factors are expressed by the diastolic pressure-time index (DPTI). If one assumes that the systolic pressure-time index (SPTI) is a rough estimate of myocardial demand, the DPTI/SPTI ratio provides an estimate of the supply/demand ratio.

There has been recent controversy about the use of SPTI as an estimate of myocardial oxygen demand,[26,27] and DPTI probably overestimates the actual mean pressure gradient across the coronary bed. Early studies demonstrated subendocardial underperfusion and histochemical evidence of subendocardial ischemia when the DPTI/SPTI ratio was less than 0.7. More recently the critical ratio has been found to approximate 0.4.[27]

Obviously, caution must be exercised when applying the results of animal studies to man. However, in our study, patients with angina pectoris and aortic stenosis,

whose DPTI/SPTI ratio was similar to that of the patients who had no angina at rest, had a reduction of this ratio below the critical value (0.38 ± 0.06) during exercise. In the patients with aortic regurgitation the DPTI/SPTI ratio at rest was significantly lower in the patients with than in those without angina. During exercise, the DPTI/SPTI ratio of the patients with angina and aortic regurgitation was below the critical ratio (0.33 ± 0.22), but the values were widely scattered and the differences insignificant.

Clinical implications: Our data indicate that coronary blood flow and myocardial uptake of oxygen remain within normal limits in patients with aortic valve disease. When patients with and without angina pectoris were compared, no differences in coronary blood flow were detected, either at rest or during exercise. Nor was any discrepancy found in either group between the pressure-time index and coronary blood flow. Thus, our data suggest that underperfusion of the subendocardial muscle is probably one of the most important factors causing angina in these patients. Our study emphasizes the need to obtain more reliable indexes to estimate this problem, because in aortic stenosis, reduction of the myocardial oxygen supply/demand ratio seems to be a fundamental mechanism in depressing left ventricular performance. Our study also emphasizes the special care needed to protect the myocardium and the subendocardium during surgical valve replacement.

Congenitally Bicuspid Aortic Valve Causing Severe, Pure Aortic Regurgitation Without Superimposed Infective Endocarditis

Analysis of 13 Patients Requiring Aortic Valve Replacement

WILLIAM C. ROBERTS, MD, FACC
ANDREW G. MORROW, MD, FACC
CHARLES L. McINTOSH, MD
MICHAEL JONES, MD
STEPHEN E. EPSTEIN, MD, FACC

Bethesda, Maryland

Although stenosis and infective endocarditis are commonly appreciated complications of the congenitally bicuspid aortic valve, pure *severe* aortic regurgitation complicating this congenital malformation, unassociated with either stenosis or infection, is not well recognized. Among 189 patients who had aortic valve replacement at the National Heart, Lung, and Blood Institute because of isolated pure aortic regurgitation, the congenitally bicuspid aortic valve, never the site of infective endocarditis, was responsible for the aortic regurgitation in 13 (7 percent). This report describes certain clinical and morphologic findings in 13 men, aged 26 to 65 years (mean 43), who required aortic valve replacement because of severe aortic regurgitation secondary to a noninfected, nonstenotic congenitally bicuspid aortic valve. Although not generally recognized, the noninfected congenitally bicuspid aortic valve is an important cause of pure aortic regurgitation severe enough to warrant aortic valve replacement.

The congenitally bicuspid aortic valve frequently becomes stenotic, and because most stenotic valves are also regurgitant, the most frequent circumstance in which aortic regurgitation is found with this congenital anomaly is in association with aortic valve stenosis.[1] In this situation the aortic regurgitation is usually of only mild or moderate degree. Also, the congenitally bicuspid aortic valve is often the site of infective endocarditis.[1] Although it may be superimposed on a stenotic congenitally bicuspid aortic valve, infective endocarditis far more commonly involves the previously normally functioning bicuspid valve or the one previously only slightly regurgitant.[1,2] The usual consequence of the infection in this circumstance is severe pure aortic regurgitation. Mild degrees of pure aortic regurgitation also are commonly observed in patients with a congenitally bicuspid aortic valve and elevated pressure in the ascending aorta from associated aortic isthmic coarctation. However, *severe* aortic regurgitation due to a nonstenotic and noninfected congenitally bicuspid aortic valve is believed to be decidedly infrequent and, indeed, no reports, to our knowledge, have focused specifically on this complication of the bicuspid valve condition. In this report, we describe observations in 13 men who underwent aortic valve replacement because of severe pure aortic regurgitation unassociated with aortic valve stenosis or infective endocarditis.

Clinical Features of Patients

Clinical findings (Table I): At the time of aortic valve replacement, the ages of the 13 men studied ranged from 26 to 65 years (mean 43). Preoperatively, one patient had been in functional class I (New York Heart Association classification[3]), three patients in class II, eight in class III and one in class IV. The one patient who was asymptomatic preop-

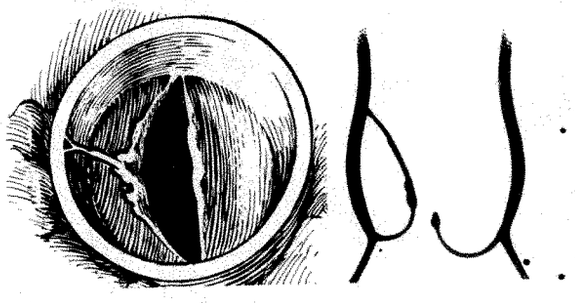
A = anterior; AV = aortic valve; AVR = aortic valve replacement; Ca^{++} = calcium; L = left; LV = left ventricle; M = murmur; P = posterior; R = right; SA = systemic artery; s/d = peak systole/end-diastole; Wt = weight; ? = not known; + = present or positive; 0 = absent or negative.

eratively underwent aortic valve replacement because of severe aortic regurgitation associated with a dilated left ventricular cavity[4] (left ventricular end-systolic cavity dimension on echocardiogram = 56 mm). None of the 13 patients at any time had had clinical evidence of either active infective endocarditis or acute rheumatic fever.

A precordial murmur had been heard for the first time initially as early as age 6 years to as late as age 60 years (mean 23). By auscultation, all 13 patients had grade 3-5/6 murmurs typical of aortic regurgitation, and by aortic root angiograms the degree of aortic regurgitation was graded in each as either 3+/4+ or 4+/4+. The direct aortic diastolic pressures preoperatively ranged from 45 to 80 mm Hg (mean 61). All 13 patients also had basal precordial systolic murmurs, but at catheterization none had a peak systolic pressure gradient between the left ventricle and a major systemic artery or on pullback from the left ventricle to the aorta. Precordial ejection sounds were absent in all 13 patients. Aortic root angiograms were obtained in all patients, but the bicuspid condition of the aortic valve could not be established by this method. Also, the bicuspid nature of the valve was not recognized in any of the seven patients who had echocardiograms.

Three patients (Cases 3, 4 and 6) had aortic isthmic coarctation, with a peak systolic pressure gradient across the coarctation of 70, 50 and 70 mm Hg, respectively. One (Patient 1) had a right aortic arch. No patient had evidence of mitral regurgitation. The father of Patient 2 had had aortic valve replacement because of a stenotic (60 mm Hg peak systolic pressure gradient) congenitally bicuspid aortic valve.

Surgical and morphologic findings: At aortic valve replacement, only two aortic valve cusps were identified in each of the 13 patients (Fig. 1 to 4). In 10 valves, a



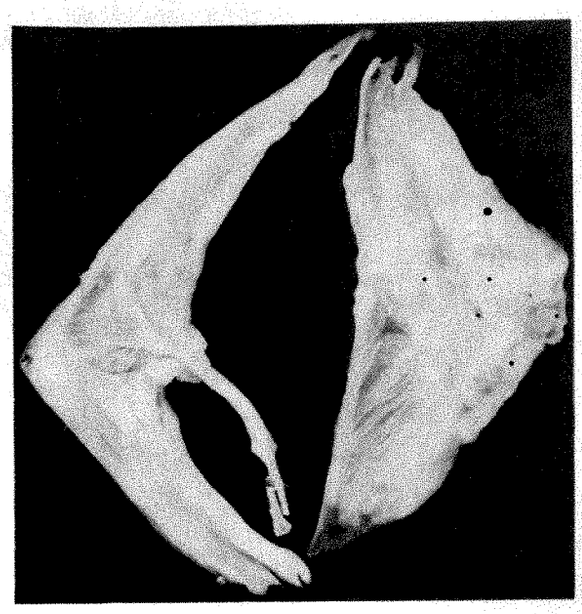


FIGURE 1. Aortic valve in Case 1. The fibrous band on the right cusp (**below**) was attached to the wall of the ascending aorta as shown in the diagram (**above**).

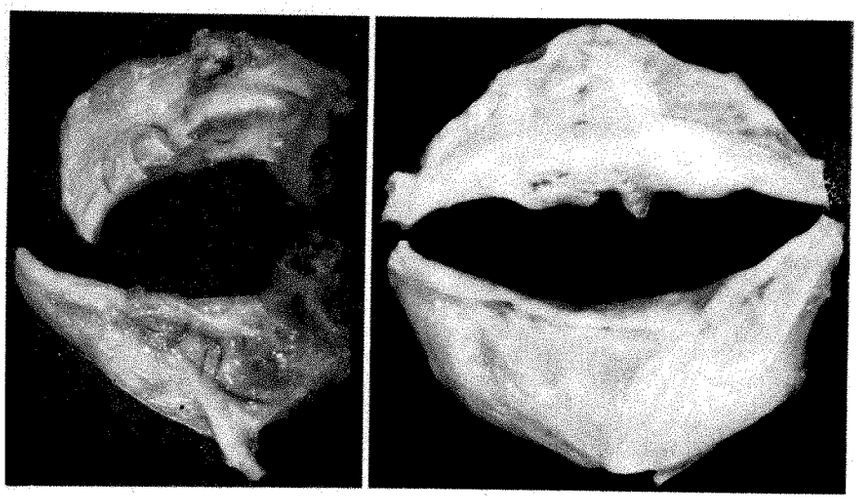

FIGURE 2. Aortic valve in Case 6 (**left**) and Case 7 (**right**). In each valve, the larger cusp is the anterior one. Calcium deposits are present in the valve on the **left**, but not in the one on the **right**.

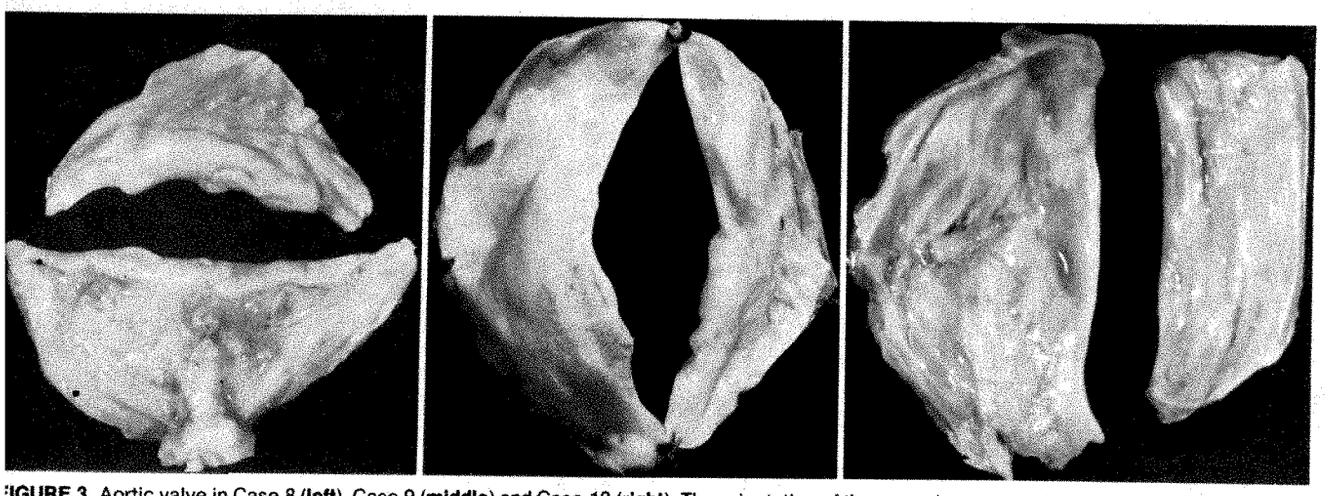

IGURE 3. Aortic valve in Case 8 (**left**), Case 9 (**middle**) and Case 13 (**right**). The orientation of the cusps is uncertain in Case 8; calcium is present n the raphe in the larger cusp. In both Case 9 and Case 13, the larger cusp is the right one, and the smaller cusp, the left one.

IGURE 4. Aortic valve in Case 12. The orientation of the two cusps this patient is not known. The raphe is calcified.

congenital raphe (false commissure) was identified. Each cusp of all 13 aortic valves was thickened by fibrous tissue; no cusp contained vegetations or perforations, indentations, or other evidences of healed infective endocarditis.[5] Calcific deposits, all small, were present in 5 of the 13 excised aortic valves; the deposits in 3 were limited to the raphes.

Comments

Frequency at necropsy of pure regurgitation in bicuspid aortic valve: Each of the 13 patients had aortic regurgitation severe enough to require aortic valve replacement, and at operation each was found to have a congenitally bicuspid aortic valve that neither was stenotic nor had evidence of past infective endocarditis. Furthermore, no patient had had a past clinical illness compatible with active infective endocarditis. Among the complications of a congenitally bicuspid aortic valve, pure severe aortic regurgitation unrelated to infective endocarditis is the least common. Among 200 patients

over age 15 years with a congenitally bicuspid aortic valve studied by one of us (W.C.R.) at *necropsy*, only 3 had pure severe aortic regurgitation unassociated with infective endocarditis.[1] Of the 200 necropsy patients, however, 179 had some degree of aortic regurgitation, but it was associated with aortic valve stenosis in 157 and was the result of infective endocarditis in 19; in the remaining 21 patients the bicuspid valve functioned normally. Of 152 necropsy patients with a congenitally bicuspid aortic valve reported on by Fenoglio et al.,[6] 4 apparently had pure aortic regurgitation without evidence of infective endocarditis; however, the severity of the aortic regurgitation in their patients was not stated.

Frequency of congenitally bicuspid valve in pure aortic regurgitation (operative experience): Although the two studies cited provide some information on the frequency of pure aortic regurgitation unassociated with infective endocarditis among *necropsy* patients with a congenitally bicuspid aortic valve, no information is available concerning the frequency of the congenitally bicuspid aortic valve unassociated with infective endocarditis among patients with pure *severe* aortic regurgitation. Accordingly, we reviewed the clinical and operative records and the excised aortic valves in 189 patients aged 18 to 70 years who had aortic valve replacement at the National Heart, Lung, and Blood Institute from 1963 to 1979 because of *isolated* (unassociated with dysfunction of another cardiac valve) *pure* (no element of valve stenosis) aortic regurgitation (Table II). In 13 (7 percent) of the 189 patients the aortic regurgitation was the result of a congenitally bicuspid aortic valve that was not and had not been the site of infective endocarditis. In contrast to the 13 patients that form the basis of this report, only 7 patients (among the 189) had pure aortic regurgitation because of infective endocarditis involving a congenitally bicuspid aortic valve. Thus, the congenitally bicuspid aortic valve unaffected by infective endocarditis is an important cause of pure aortic regurgitation severe enough to warrant aortic valve replacement.

TABLE II

Etiology of Isolated Pure Aortic Regurgitation in 189 Patients Aged 18 to 70 Years Having Aortic Valve Replacement

Cause	Patients n	Patients %
1.* Rheumatic	94	49
2.* Infective endocarditis	41	22
Bicuspid (n = 7)		
Tricuspid (n = 34)		
3. Marfan and Marfan-type	15	8

MARY HALL-CRAIGS, MD
DAVID C. GREEN, MD
ROBERT T. SINGLETON, MD, FACC
PETER H. WIERNIK, MD

Baltimore, Maryland

Delayed chronic constrictive pericarditis developed in seven patients 51 to 268 (mean 116) months after radiotherapy. Six of the seven complained of exertional dyspnea that was initially believed to be caused by mediastinal fibrosis. All patients had raised jugular venous pressure, although in two patients this finding was not appreciated by the primary physician. There were no consistent noninvasively identifiable features to allow prediction of constrictive pericarditis other than consideration of its existence and careful examination of the cardiovascular system. All patients had constrictive pericarditis proved at cardiac catheterization. Of the five patients who underwent pericardiectomy, two had an excellent functional result, one has residual pericardial constriction and two died of unrelated causes. Recommendations for the treatment of radiation-induced pericardial disease are given.

Supervoltage radiation therapy has been administered for more than 2 decades to patients who have breast cancer or Hodgkin's disease. As these patients have established extended survival patterns and cures from their malignancy, the delayed cardiac consequences of this treatment have become recognized. It is generally accepted that transient pericardial effusions represent the most common form of radiation-induced cardiac disease and may be found in as many as 30 percent of patients.[1] This entity characteristically develops within the first 24 months after radiotherapy and usually resolves spontaneously within 2 years without any chronic sequelae.[1,2] Less frequently, effusive-constrictive or chronic constrictive pericarditis may occur. Among 21 patients receiving mediastinal radiotherapy, effusive constrictive pericarditis was noted in 6 patients and chronic constrictive pericarditis in 3.[3] The interval between radiotherapy and the diagnosis of either effusive-constrictive or chronic constrictive pericarditis in that series ranged from 6 to 72 (mean 26.5) months. No instances of such complications were found in another study[2] encompassing 81 patients. Despite the experience indicating the appearance of radiation-induced pericardial disease relatively soon after radiotherapy,[1,2] there have been instances of its delayed occurrence.[3–5] This report emphasizes the clinical spectrum of pericardial disease after mediastinal irradiation as well as the potential for delayed appearance of the disease. The possible pathogenesis of delayed radiation-induced pericardial disease and our recommendations for its treatment are discussed.

Study Patients

Seven patients at the Baltimore Cancer Research Program—National Cancer Institute who manifested radiation-related pericardial disease 51 to 268 (mean 116) months after radiotherapy form the basis of this study. Five of these seven (Cases 2 to 4, 6 and 7) are from a larger group of 81 patients who had Hodgkin's disease treated (before 1974) by anteriorly weighted thoracic mantle radiotherapy; one patient (Case 1) was identified from approximately 70 patients who had Hodgkin's disease treated (since 1974) and had received modified anteriorly weighted thoracic mantle radiotherapy; one patient (Case 5) had received 28 courses of an unknown amount of thoracic radiation 16 years earlier for breast carcinoma. The predominance of Hodgkin's disease in this series reflects a se-

* At time definitive diagnosis of pericardial disease was made. † Therapy given as mid cardiac dose (rads)/numbers of days total course of radiotherapy given. ‡ Interval (in months) from completion of radiotherapy to recognition of radiation-induced pericardial disease. § Calculated using shortest interval from radiotherapy to confirmed diagnosis of pericardial disease.

Adm = adriamycin; CCP = chronic constrictive pericarditis; CNU = lomustine; CVPP = cyclophosphamide, vincristine, procarbazine, prednisone; E-CP = effusive-constrictive pericarditis; HD = Hodgkin's disease; 3A$_{EL}$ = stage 3A of Hodgkin's disease with limited extension to the lungs; MOPP = nitrogen mustard, vincristine, procarbazine, prednisone; NS = nodular sclerosis; VBL = vinblastine.

lection bias of our institution. The mid cardiac radiation dose in the six patients treated for Hodgkin's disease was 3,874 to 4,905 (mean 4,513) rads. In the patient treated for breast carcinoma 16 years before entry, the radiation dose was unknown. No cause (infectious, neoplastic, collagen vascular or metabolic) for the pericardial reactions other than irradiation was present in any of these seven patients. Although all patients were also treated with chemotherapy, known cardiotoxic drugs were used only in Patient 5, and no evidence of drug-induced cardiac toxicity was found in this patient at autopsy.

Results

Clinical features: The clinical data on the seven patients are summarized in Table I. Five patients (Cases 2 to 5 and 7) complained of moderately severe effort dyspnea; however, only two of them (Cases 5 and 7) had significant mediastinal fibrosis on their chest X-ray film. One patient (Case 6) manifested unexplained pleural effusions and hepatosplenomegaly 9 months before choronic constrictive pericarditis was diagnosed. He was being evaluated for a possible recurrence of his Hodgkin's disease until it was recognized that these signs were caused by chronic constrictive pericarditis. Another patient (Case 1) had signs of acute pericarditis (fever and a pericardial friction rub) and had evidence of cardiac tamponade. A diagnostic surgically produced pericardial window revealed a 500 cc serous pericardial effusion and moderately thickened pericardium (that is, effusive-constrictive pericarditis). Three months after the pericardial window was performed for cardiac tamponade, a Swan-Ganz catheterization showed evidence of constrictive pericarditis. Pericardial effusions were documented 1, 4, 24, and 72 months, respectively, before the diagnosis of chronic constrictive pericarditis in four patients (Cases 3 and 5 to 7). The data from these five patients (Cases 1, 3 and 5 to 7) suggest that chronic constrictive pericarditis occurring after mediastinal radiotherapy is usually preceded by an effusive pericardial reaction that may be present many months earlier.

Noninvasive diagnostic signs: When constrictive pericarditis was diagnosed, all patients had a raised mean jugular venous pressure (more than 10 cm water) by physical examination with collapsing X/Y descent. Two patients (Cases 2 and 4) had a pericardial knock and two (Cases 2 and 3) had distant heart sounds. Noninvasive studies (electrocardiography and M mode echocardiography) did not consistently predict the presence of chronic pericardial disease in these severe patients. The total summed limb lead QRS amplitude by electrocardiogram taken before irradiation as compared with that at the time chronic constrictive pericarditis was diagnosed showed a reduction of 13 to 5 (mean 40.3) percent in six patients (Cases 1 to 3 and 5 to 7) and an increase of 50 percent in one patient (Case 4). All echocardiographic chamber measurements were

ormal; four patients (Cases 2 to 4 and 6) had paradoxical interventricular septal motion. No patient displayed the "dip-plateau" pattern in the posterior left ventricular wall motion described by others.[6] At cardiac catheterization (Table II), all patients had hemodynamic data compatible with constrictive pericarditis.

Surgical treatment: Five patients (Cases 2, 3 and 5 to 7) underwent pericardiectomy. The indication for operation was incapacitating exertional dyspnea in four patients (Cases 2, 3, 5 and 7) and persistent pulsatile hepatomegaly in one patient (Case 6). Two patients died after operation, one patient (Case 5) two weeks later from respiratory insufficiency caused by pulmonary fibrosis and lymphangitic spread of her breast carcinoma, and the other (Case 7) 3 months later from progressive Hodgkin's disease of the lungs and chemotherapy-induced granulocytopenia. These two patients showed an initial increase (5 to 10 mm Hg) in systolic blood pressure and decrease (3 to 5 cm H_2O) in mean jugular venous pressure postoperatively. There was little change in the degree of dyspnea in either of them. At autopsy, there was no evidence of myocardial fibrosis in either patient; one patient (Case 5) had some residual visceral pericardial constriction.

Two of the three surviving patients (Cases 2 and 3) are doing well 4 and 12 months, respectively, after operation without clinical evidence of pericardial constriction. Their systolic blood pressure has increased by 5 to 13 mm Hg and their mean jugular venous pressure has decreased by 6 to 10 cm H_2O. A third patient (Case 4) has had no significant changes in blood pressure, heart rate, mean jugular venous pressure or degree of hepatomegaly over an 18 month period after his pericardiectomy. A repeat cardiac catheterization has shown hemodynamic evidence of constrictive pericarditis and is believed to have visceral pericardial constriction. The one patient (Case 4) not having surgery has had no significant changes in symptoms, physical findings or hemodynamic measurements during a 21 month follow-up period. She is not being treated with either digitalis or diuretic agents.

Pathology: Review of the pericardial specimens in all of the operative cases revealed thickening and fibrosis. There was no evidence of significant endomyocardial fibrosis in a biopsy of the interventricular septum (Patient 6) or at autopsy in the two patients (Cases 5 and 7) who died. We believe that these morphologic observations make restrictive endomyocardial disease an unlikely cause for the hemodynamic findings in any of these seven patients.

Discussion

Incidence: Previous studies have reported the incidence of radiation-induced pericardial disease to range from 7.7[3,4] to 30[1,2] percent in patients treated with mediastinal irradiation. Characteristically, this entity occurs within the initial 24 to 36 months after radiotherapy and is either an effusive or effusive-constrictive pericarditis. Three of 21 patients with radiation-induced cardiac disease in one study[3] manifested chronic constrictive pericarditis associated with endomyocardial fibrosis 36 to 72 (mean 51) months after mediastinal irradiation. Earlier reports[1,2] from our center included no instances of chronic constrictive pericarditis although the potential for development of this complication was recognized. Our present study indicates that the cardiac consequences of thoracic irradiation may be delayed in appearance for more than 48 months after treatment. Indeed, even if the patient treated with an unknown amount of radiation is excluded from consideration, our patients still experienced a mean interval of 82.8 months between radiotherapy and the earliest clinical recognition of *any* form of heart disease. These delayed cardiac reactions are generally not appreciated by physicians caring for patients who have received mediastinal radiotherapy. Further, none of the patients in the present study were included in an earlier report from our center. In that study,[1] the incidence rate of radiation-induced pericardial effusions in 81 consecutive patients treated with radiotherapy for Hodgkin's disease between 1968 and 1972 was 30.9 percent (25 of 81). Thus, the incidence rate of any type of radiation-induced pericardial disease in these 81 patients is at least 38 percent (31 of 81). We are in the process of performing detailed cardiac evaluations in this entire cohort of 81 patients. It should be reemphasized that six of the seven patients in our study (all but Case 5), as well as all of those previously reported on,[1] were treated by anteriorly weighted or modified anteriorly weighted thoracic mantle field techniques. A potential limitation of these techniques, which is substantiated by our experience, is the production of higher average mid cardiac levels of radiation. Since 1975 equally opposed mantle fields have been employed at our center with a resultant decrease in the average radiation dose received by the heart. Although we have observed a small number of transient pericardial effusions in this group, as yet no instances of effusive-constrictive or chronic constrictive pericarditis have been seen (study in progress).

Pathogenesis: The pathogenesis of radiation-induced myocardial disease has been shown in experi-

mental studies to be caused by a "microvascular ischemia" [4] in which the myocardial capillary bed is obliterated by endothelial cell swelling. The consequence of these changes is ischemia to the myofiber with resultant myocardial fibrosis. By contrast, the pathogenesis of radiation-induced pericardial disease has not been adequately delineated. In addition to the radiotherapy technique used, reactivation of a latent virus within the pericardium,[1] the obstruction of pericardial lymphatics as a consequence of radiotherapy with a resultant effusive pericarditis that organizes and becomes fibrotic,[1] or potentiation of an as yet undefined type of pericardial reaction by adjunctive use of chemotherapeutic agents[1] are possible mechanisms. Further, it is uncertain why radiation-induced pericardial disease appears relatively soon (within months) after irradiation in some patients and may be delayed for extended periods (several years) in other patients. These observations suggest that several different pathophysiologic mechanisms may be responsible for radiation-induced pericardial disease.

Diagnostic clinical features: The recognition of radiation-induced pericardial disease necessitates an awareness of its possible occurrence at any time by physicians caring for patients treated previously with mediastinal irradiation. Six patients (Cases 1 to 5 and 7) in our study experienced dyspnea, and this symptom was incapacitating in four of them (Cases 2, 3, 5 and 7). In two of the four (Cases 5 and 7) chest x-ray examination revealed severe pulmonary fibrosis that was initially believed to be the cause of their dyspnea. The two other patients (Cases 2 and 3) had dyspnea only on strenuous effort. All patients in this study had raised jugular venous pressure with collapsing diastolic descent. In two patients, the external jugular veins were collapsed at a time when the pressure in the internal jugular venous system was 15 cm H_2O. It was not until this discrepancy was sought by careful examination of the jugular veins that the correct diagnosis was made in these patients. Diminished intensity of the heart sounds, the presence of a pericardial knock and diminished QRS voltage in the limb leads were infrequently noted. Paradoxical interventricular septal motion by echocardiography was also not a sensitive finding, being present in only four (Cases 2, 3, 4 and 6) of seven patients.

Nonetheless, a characteristic clinical picture emerges of effusive-constrictive or chronic constrictive pericarditis occurring after mediastinal irradiation. Patients will have mild to moderate exertional dyspnea with or without pleural effusions, hepatomegaly or peripheral edema. All will have raised jugular venous pressure, and some will have distant quality heart sounds. An electrocardiogram often shows diminished QRS amplitude in the limb leads. The echocardiogram will demonstrate a pericardial effusion and thickened pericardium or paradoxic interventricular septal motion, or both, in the patient who has effusive constrictive pericarditis. Cardiac catheterization in these instances will demonstrate diastolic equalization of right heart pressures. Pericardial effusion is usually not found on echocardiography in patients who have constrictive pericarditis although a thickened pericardium or paradoxic interventricular septal motion, or both, may be noted. Except by the absence of known tumor recurrence elsewhere or a long elapsed period of time after initial therapy of the malignancy, it is not possible on clinical grounds to differentiate radiation-induced pericardial disease from pericardial reactions caused by tumors.

Recommendations for treatment: Our therapeutic approach to patients who have radiation-induced pericardial disease is predicated on their symptoms and underlying pericardial process. In patients who have cardiac tamponade (that is, dyspnea and hypotension and an echocardiographically confirmed pericardial effusion, we advise a surgically produced subxiphoid pericardial window. In patients with incapacitating effort dyspnea, fatigue or marked hepatomegaly (liver more than 16 cm in span), we advise pericardiectomy if constrictive pericarditis is confirmed by cardiac catheterization. We do *not* currently advise surgery solely on the basis of hemodynamic confirmation of constrictive pericarditis or for the presence of recurrent pleural effusions. This approach has not led to an increased morbidity from myocardial fibrosis at our center. Objective clinical and hemodynamic data in one of our patients (Case 4) who has had no substantial changes in her evaluation over a 21 month period support this approach. Further, data[8] from patients with constrictive pericarditis caused by tuberculosis do not indicate an increased risk of myocardial fibrosis if pericardiectomy is delayed. Our recommendations are at variance with those of others[9] who advise pericardiectomy soon after the hemodynamic confirmation of radiation-induced effusive constrictive or chronic constrictive pericarditis.

Eleven patients, 10 male, with classic hypertrophic obstructive cardiomyopathy and lentiginosis are described. Physical examination showed differences from the few previously reported cases in that (1) this condition was not confined to children; (2) mental retardation, sensorineural deafness and gonadal and somatic infantilism were either rare or absent; and (3) detailed family studies provided no evidence that this condition was inherited. Nine patients underwent cardiac catheterization and left ventricular angiography; all had left ventricular outflow obstruction and three had concomitant right ventricular outflow obstruction with a pressure gradient in excess of 100 mm Hg. Ten of the 11 patients were severely symptomatic, and 7, each with a left ventricular pressure gradient of more than 70 mm Hg, underwent successful septal myotomy/myectomy that resulted in marked symptomatic improvement that was maintained after long-term follow-up.

Hypertrophic obstructive cardiomyopathy has been described in association with several anomalies of neural crest tissue, such as pheochromocytoma,[1] tuberous sclerosis[2] and neurofibromatosis.[3] These associations, together with the hemodynamic changes induced by catecholamines, led to speculation that the cause of hypertrophic obstructive cardiomyopathy might lie in a disturbance of the sympathetic nerve supply to the heart. A less well known neuroectodermal association described by Moynahan and Polani[4–6]—that of hypertrophic obstructive cardiomyopathy and lentiginosis, a disorder of the pigmentary elements of the skin—seemed to lend credibility to such etiologic speculations. This syndrome, which they called "cardiomyopathic lentiginosis," occurred in children, was reported to be dominantly inherited, and was associated with sensorineural deafness, genital hypoplasia and psychic and somatic infantilism.

In this report we describe 11 patients with hypertrophic obstructive cardiomyopathy and lentiginosis who differed in the following major respects: (1) The majority were adults; (2) deafness, psychic, sexual and somatic infantilism were either rare or absent; and (3) detailed clinical and echocardiographic family studies revealed no evidence of dominant inheritance.

Patients

Of the 11 patients with hypertrophic obstructive cardiomyopathy and lentiginosis, 10 were male and 1 was female. Their ages ranged from 16 months to 69 years (mean 43 years). The diagnosis of hypertrophic obstructive cardiomyopathy was made in 9 patients with cardiac catheterization studies indicating the presence of a left ventricular outflow tract gradient at rest; in 10 patients the diagnosis was made with echocardiographic studies showing the presence of asymmetric septal hypertrophy, systolic anterior motion of the mitral valve or mid-systolic aortic valve closure.

Results

Symptoms (Table I): All but one of the 11 patients were symptomatic; 6 had central chest pain related to exertion, 5 had grade II to IV exertional dyspnea (New York Heart Association Classification[7]) and 6 had

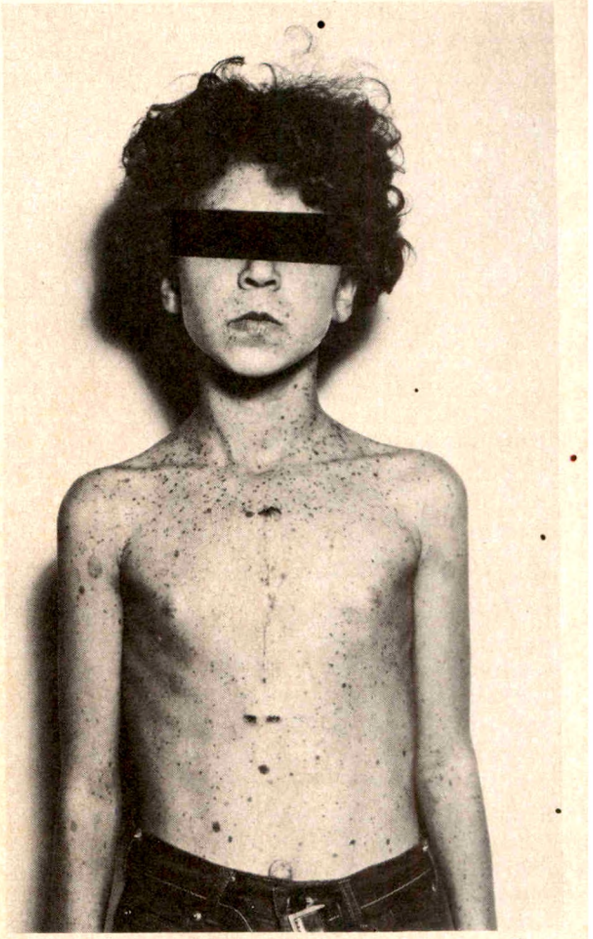

FIGURE 1. Twelve year old patient with diffuse lentiginosis and hypertrophic cardiomyopathy resulting in severe obstruction of both ventricular outflow tracts. Note the numerous dark brown spots distributed over the face, chest, trunk and back. This patient had recently undergone myotomy/myectomy successfully.

near or complete syncope. The only asymptomatic patient was referred to the Division of Cardiology for investigation of a systolic ejection murmur at the left sternal border.

Clinical examination (Table I): The most striking feature on examination, particularly in the younger patients, was the presence of lentigines, which were dark brown to black, bilaterally distributed, round or polycyclic macules appearing mainly on the trunk and limbs and sometimes on the face (Fig. 1). These lesions were diagnosed clinically by their classic appearance, and in the first seven patients they were confirmed by skin biopsy. All patients had jerky or sharp upstrokes of the carotid pulses, thrusting apical beats, and a systolic ejection murmur at the left sternal border, suggesting left ventricular outflow tract obstruction due to hypertrophic obstructive cardiomyopathy. One patient, aged 1.5 years, was at the third percentile for height and weight and had sensorineural deafness.

Chest roentgenograms revealed marked cardiomegaly (cardiothoracic ratio more than 0.55) in seven patients. Electrocardiograms were abnormal in all patients: seven had left ventricular hypertrophy, four left axis deviation, one severe right ventricular hypertrophy and one biventricular hypertrophy.

Echocardiograms (Table I): Echocardiograms were obtained in 10 patients. However, four of these were performed postoperatively and the remaining six were preoperative, but all showed systolic anterior motion of the mitral valve and asymmetric septal hypertrophy; in addition, five demonstrated mid systolic aortic valve closure.

Hemodynamics (Table II): All nine patients who had cardiac catheterization had typical hemodynamic and angiographic features of obstructive cardiomyopathy. Left ventricular end-diastolic pressure ranged from 6 to 18 mm Hg and was normal in three patients. A left ventricular outflow tract gradient at rest was present in all patients and ranged from 27 to 150 mm Hg. Three patients had, in addition, a right ventricular outflow tract gradient at rest in excess of 100 mm Hg, and one of the three had a left coronary arterial aneurysm but otherwise normal coronary arteries.

Management: Seven of the 11 patients, each with a resting left ventricular outflow tract gradient of more than 70 mm Hg and symptoms of angina or syncope, underwent septal myotomy/myectomy. There were no operative or late deaths, and all seven patients manifested marked symptomatic benefit in the postoperative follow-up period, which ranged from 1 to 12 years. Three of the four patients treated conservatively are taking propranolol, two patients have continued with propranolol postoperatively, and the asymptomatic patient is not receiving any medication.

Family history: Detailed clinical family histories of each propositus and echocardiographic examinations of five families and their close relatives failed to demonstrate a history of lentiginosis, heart disease or increased incidence of sudden death.

TABLE II

Hemodynamic Findings in Nine Cases

Case	Age (yr)	LVEDP (mm Hg)	LVOT Gradient (mm Hg)		RVOT Gradient at Rest (mm Hg)
			At Rest	After Isoproterenol	
1	32	10	74	100	...
2	69	18	30	55	...
3	20	16	75	...	...
4	35	17	60	120	...
5	9	17	150	...	120
6	55	6	95	...	...
7	20	17	27	78	...
8	1.5	9	106	...	107
9	12	15	86	...	105

LVEDP = left ventricular end-diastolic pressure; LVOT = left ventricular outflow tract; RVOT = right ventricular outflow tract.

Discussion

Initial speculations that the cause of hypertrophic obstructive cardiomyopathy was a disturbance of the sympathetic nerve supply to the heart—based on its predictable response to sympathomimetic catecholamines and its associations with neural crest anomalies—have not been substantiated. In the majority of patients, hypertrophic obstructive cardiomyopathy is transmitted by simple autosomal dominant inheritance with varying penetrance and phenotypic expression,[8] and when first reported it appeared to be no different when it was associated with lentiginosis.

Lentiginosis is a disorder of skin pigmentation that is of neural crest origin.[6] It consists of multiple brown to black macules bilaterally distributed on the trunk, limbs and face; the macules are not confined to surfaces exposed to sunlight, being present often on the palms, soles and hairy scalp. These lesions are clinically distinguishable from ephelides (freckles) because, unlike freckles, they do not darken or increase on exposure to sunlight, and they occur at or soon after birth—that is, before freckles, which appear between 4 and 6 years—and increase in number until puberty.[4,6] Skin biopsy shows characteristic histologic features, which were present in all our patients, namely (1) corrugation of the dermoepidermal junction due to invagination of the dermis by elongated rete pegs, (2) accumulation of pigment in the dermis and in the cells of the deeper and upper layers of the epidermis, and (3) increased numbers of melanocytes per unit area of skin.[6,8]

Previously reported cardiac disease in lentiginosis: Lentiginosis was first described 30 years ago as a family occurrence associated with nystagmus,[9] but no connection with cardiac disease was recognized until 1966, when Walther et al.[10] and then Matthews[11] each reported on three members of a family in two generations who had multiple lentigines, systolic murmurs, intraventricular conduction disturbances and T wave abnormalities suggesting myocardial infarction. The cause of the murmurs and electrocardiographic abnormalities, both of which were constant features in the two pedigrees, was not elucidated at the time. Subsequently, two new syndromes were postulated: cardiomyopathic lentiginosis[4,6] and leopard[12] or little leopard syndrome.[13] These two syndromes have so many features in common—(1) genital hypoplasia represented by cryptorchidism, ovarian dysgenesis and hypospadias; (2) sensorineural deafness; (3) psychic and somatic infantilism; and (4) dominant inheritance—that it seemed likely that they are one and the same disease entity. However, there was disparity as to the exact nature of the heart disease; several investigators[4,6,14–16] suggested hypertrophic obstructive cardiomyopathy; others[12,13,17] favored right ventricular outflow tract obstruction due to mild pulmonary stenosis.

Closer scrutiny of the clinical findings in the patients thus far described failed to distinguish between cardiomyopathic lentiginosis and leopard syndrome in terms of abnormal signs in the cardiovascular system. Few patients with leopard syndrome were investigated further than with right heart catheterization,[10–13] and even then the procedure did not always include angiography, and these patients were reported to have right ventricular outflow tract obstruction at the valve or subvalve level. By contrast, most patients with cardiomyopathic lentiginosis had right and left heart catheterization with biventricular angiography, which demonstrated left ventricular outflow obstruction due to hypertrophic obstructive cardiomyopathy.[6,14,16] Usually in hypertrophic obstructive cardiomyopathy, left-sided signs and appropriate electrocardiographic features dominate the clinical findings, but in patients with lentiginosis, right-sided signs may predominate, as in one of Somerville and Bonham-Carter's patients[14] and in one of our patients who had the physical findings of severe right ventricular outflow tract obstruction and extreme right ventricular hypertrophy on electrocardiography. It is thus not surprising that the clinical diagnosis of pulmonary stenosis was suggested.

Clinical features and diagnosis: With regard to the skin lesions, there was marked individual variation in the number of lentigines present (from hundreds to thousands) and, although their appearance and distribution were constant, which made differentiation from ephelides and café-au-lait spots easy, the diagnosis in some patients was obvious, but in others it was much more subtle. In all but one child, body habitus was normal and height and weight percentiles were within normal limits, and no patient had any evidence of gonadal hypoplasia. However, the one child with somatic infantilism was intellectually retarded, but this may have been related to bilateral sensorineural deafness, which occurred only in this patient. The rarity or absence of the features initially described as forming a part of the syndrome of cardiomyopathic lentiginosis[4–6] and leopard syndrome[12,13,17] is in sharp contrast to previous reports and deserves mention so that in their absence the diagnosis is not overlooked.

Our patients differed from those previously reported in several important respects: (1) There was an over-

whelming male preponderance. (2) Hitherto the association of hypertrophic obstructive cardiomyopathy and lentiginosis had not been fully documented in adults and is here described in patients of all ages from infancy to old age. (3) Clinical histories of each propositus and the pedigree and echocardiographic examination of all available close relatives of five families revealed no other family member with either hypertrophic obstructive cardiomyopathy or lentiginosis and thus showed that it is very unlikely that the mode of inheritance of this syndrome is by mendelian dominance. (4) Genital hypoplasia, deafness and psychic and somatic infantilism were rare.

Hypertrophic obstructive cardiomyopathy: We submit that in view of the large number of common features, cardiomyopathic lentiginosis and leopard syndrome are the same disease entity and that the cardiac lesion common to both is hypertrophic obstructive cardiomyopathy. In 30 percent of patients, right ventricular outflow tract obstruction is also present. The presence of lentiginosis, electrocardiographic abnormalities and a systolic murmur should raise the clinical suspicion of coexistent hypertrophic obstructive cardiomyopathy, and patients with these findings warrant full investigation and treatment. Thus, the diagnosis of cardiomyopathic lentiginosis should not be overlooked in adults in the absence of sensorineural deafness or psychic, sexual, or somatic infantilism.

Although we have seen patients with diffuse lentiginosis with no evidence of heart disease (and normal echocardiographic findings), some of these patients have heart disease other than hypertrophic cardiomyopathy. Thus, we have seen lentiginosis associated with atrial myxoma (one patient), coarctation of the aorta (one patient), aortic valve stenosis (one patient) and undefined cardiomyopathy (one patient). We believe that these examples represent chance occurrences of two distinct and separate disease entities rather than a specific relation of the type postulated for lentiginosis and hypertrophic obstructive cardiomyopathy.

History and Physical Examination in Acute Pulmonary Embolism in Patients Without Preexisting Cardiac or Pulmonary Disease*

PAUL D. STEIN, MD, FACC†
PARK W. WILLIS, III, MD, FACC‡
DAVID L. DeMETS, PhD§

Detroit, Michigan
Bethesda, Maryland

The history and physical examination were assessed in 215 patients with acute pulmonary embolism uncomplicated by preexisting cardiac or pulmonary disease. The patients had been included in the Urokinase Pulmonary Embolism Trial or the Urokinase-Streptokinase Embolism Trial. Presenting syndromes were (1) circulatory collapse with shock (10 percent) or syncope (9 percent); (2) pulmonary infarction with hemoptysis (25 percent) or pleuritic pain and no hemoptysis (41 percent); (3) uncomplicated embolism characterized by dyspnea (12 percent) or nonpleuritic pain usually with tachypnea (3 percent) or deep venous thrombosis with tachypnea (0.5 percent). The most frequent symptoms were dyspnea (84 percent), pleuritic pain (74 percent), apprehension (63 percent) and cough (50 percent). Hemoptysis occurred in only 28 percent. Dyspnea, hemoptysis or pleuritic pain occurred separately or in combination in 94 percent. All three occurred in only 22 percent. The most frequent signs were tachypnea (respiration rate 20/min or more) (85 percent), tachycardia (heart rate 100 beats/min or more) (58 percent), accentuated pulmonary component of the second heart sound (57 percent) and rales (56 percent). Signs of deep venous thrombosis were present in only 41 percent and a pleural friction rub was present in only 18 percent. Either dyspnea or tachypnea occurred in 96 percent. Dyspnea, tachypnea or deep venous thrombosis occurred in 99 percent. As a group, the identified clinical manifestations, although nonspecific, are strongly suggestive of acute pulmonary embolism. Conversely, acute pulmonary embolism was rarely identified in the absence of dyspnea, tachypnea or deep venous thrombosis.

An array of nonspecific abnormalities has been identified which has been shown to be suggestive of acute pulmonary embolism.[1–8] It is now well recognized that one cannot rely on the traditional symptoms of hemoptysis and pleuritic pain, which are indicative of pulmonary infarction, to diagnose acute pulmonary embolism.[1–8] How, then, can one make the diagnosis? It has been suggested[9] that by clinical means, one cannot make the diagnosis with any degree of reliability because the clinical manifestations are elusive. It was further suggested, therefore, that greater reliance should be placed on pulmonary arteriography.[9] Unfortunately, pulmonary arteriography is not without morbidity, although the risk is low.[3,10] Certainly it is expensive. Moreover, a variety of circumstances limit its diagnostic value. These include obesity, inability of the patient to lie flat or hold still and inability of the patient to hold his breath. Small emboli are difficult to detect by arteriography, and may require several injections as well as specialized techniques such as cinearteriography[11] or wedge arteriography.[12] Arteriographic abnormalities also occur in primary pulmonary disease.[13] Such abnormalities require differentiation from the abnormalities of pulmonary embolism, which, particularly with small distal emboli, require refined techniques

and still may not be possible to diagnose. The exclusion of pulmonary embolism therefore requires a procedure that itself imposes discomfort and risk on the patient.

Pulmonary arteriography is not a procedure to be employed without strong evidence that pulmonary embolism may be present. If one assumes that pulmonary arteriograms would not be obtained without a strong suspicion of pulmonary embolism, the reported high prevalence rate of negative pulmonary arteriograms (60 percent in one group,[14] 73 percent in another[9]) indicates an inability to exclude acute pulmonary embolism by clinical methods or an inability to identify patients in whom acute pulmonary embolism is likely.

Although several reports have enumerated the signs and symptoms of acute pulmonary embolism, few have described patients who are free of preexisting cardiac or pulmonary disorders.[5,6] Therefore, the clinical manifestations of acute pulmonary embolism itself, and not the manifestations of other diseases frequently associated with pulmonary embolism, may not be clear from such previous studies. In view of the opinion that pulmonary embolism is highly elusive,[9] the purpose of this study was to determine the clinical manifestations of acute pulmonary embolism in patients with no coexisting cardiac or pulmonary disease. It was hoped that syndromes of acute pulmonary embolism could be identified that would lead to a strong presumptive clinical diagnosis. The potential value of such an investigation is to improve the selection of patients for pulmonary arteriography and thereby reduce the number of false negative examinations.

Methods

Study patients: Two hundred fifteen adults without previous cardiac or pulmonary disorders were identified among the 327 patients included either in the Urokinase Pulmonary Embolism Trial[10] or in the Urokinase-Streptokinase Embolism Trial.[15] Each patient had arteriographically defined acute pulmonary embolism with symptoms for no more than 5 days before the pulmonary arteriogram. The physical findings reported were those noted when the pulmonary embolism was initially suspected.

All of the patients were 18 years of age or older. Patients were excluded from these studies of thrombolytic agents if they had a surgical procedure within 10 days of the diagnosis, had severe systemic hypertension, severe renal or hepatic insufficiency, a cerebral vascular accident within 2 months or an actively bleeding lesion in the gastrointestinal or genitourinary tract or if they were pregnant or were in the first 10 days after delivery.[10,15] Therefore, the identification of the prevalence of these predisposing factors in this experience is limited.

Assessment of severity of pulmonary embolization: The patients in the Urokinase Pulmonary Embolism Trial or in the Urokinase-Streptokinase Embolism Trial were categorized as having either massive pulmonary embolism (obstructions or filling defects involving two or more lobar arteries or the equivalent) or submassive embolism (obstruction or significant filling defect involving at least one segmental pulmonary artery but less than the equivalent of two lobar arteries).[10,15] The severity of the pulmonary embolization was assessed from the pulmonary arteriograms with use of a objective index.[16]

Clinical manifestations: We evaluated the clinic manifestations in 215 patients without preexisting cardiac pulmonary disease. Specifically, patients were excluded if the had a history of myocardial infarction, angina pectori rheumatic heart disease, congestive heart failure for more tha 7 days, other heart disease, primary pulmonary disease systemic hypertension. Each of the characteristics of th history and physical examination that we report was specif cally noted in questionnaires that were completed when th patient entered the study immediately after completion of th pulmonary arteriogram. The diagnosis of deep veno thrombosis was based on clinical findings; venography was n required. The diagnosis of shock was made on the basis blood pressure and associated signs and symptoms. The fr quency of each sign and symptom refers to the percent patients who had the sign or symptom relative to the numb of patients for whom the information was recorded. Becau it was impossible from previous reports to determine th physical characteristics of patients without previous cardi or pulmonary disease, an entirely new analysis of the prima data was required for this study.

Results

Symptoms and physical signs: Dyspnea occurre in 84 percent of the patients and was the most frequer symptom of acute pulmonary embolism. Pleuritic pai apprehension and cough each occurred in at least ha of the patients (Table I). The most frequent sign acute pulmonary embolism was tachypnea (85 percen (Table II). Tachycardia (heart rate 100 beats/min more), an accentuated pulmonary component of th second heart sound, rales, and fever (temperature 37.5 C or more) each occurred in about half of the patient Deep venous thrombosis was identified in 41 percent the patients. A pleural friction rub was uncommon (1 percent). The occurrence of rales in more than half the patients indicates that their presence is a sign acute pulmonary embolism and is not necessarily du to accompanying disorders.

Combinations of signs and symptoms were identified that assisted in assessing the likelihood of pulmonary embolism. Either dyspnea or tachypnea occurred in the vast majority of patients (96 percent). Dyspnea, tachypnea or deep venous thrombosis was present in 99 percent of patients. Acute pulmonary embolism was rarely encountered in the absence of dyspnea, tachypnea or deep venous thrombosis.

The combination of dyspnea and pleuritic pain and hemoptysis occurred in only 22 percent of patients (*Table III*). However, dyspnea and pleuritic pain were common (40 percent). Six percent of patients had no dyspnea, pleuritic pain or hemoptysis.

Presenting syndromes of acute pulmonary embolism: The presenting characteristics of these patients were divided into groups according to the most representative syndromes of acute pulmonary embolism (Table IV). These presenting syndromes are named and listed according to the most serious clinical characteristics. Thus, patients with circulatory collapse manifested by shock also may have had hemoptysis. However, those characterized as having pulmonary infarction with hemoptysis would not have had shock according to this method of classification. (1) The circulatory collapse syndromes of acute pulmonary embolism included shock, which occurred in 10 percent of patients and syncope without shock, which occurred in 9 percent. (2) The pulmonary infarction syndromes included hemoptysis with or without pleuritic pain, which occurred in 25 percent of patients, and pleuritic pain not accompanied by hemoptysis, which occurred in 41 percent of patients. (3) Uncomplicated pulmonary embolism, which was defined as acute pulmonary embolism without circulatory collapse or symptoms of pulmonary infarction, typically was characterized by dyspnea, and this syndrome occurred in 12 percent of patients. Uncomplicated pulmonary embolism characterized by nonpleuritic pain, usually with tachypnea, occurred in 3 percent of patients. One patient (0.5 percent) had symptoms of deep venous thrombosis and tachypnea without dyspnea or chest pain. The most frequent symptoms and signs that accompanied these presenting syndromes of acute pulmonary embolism are listed in Table V. Only one patient (0.5 percent) in the entire group had congestive heart failure, apparently as a result of the acute pulmonary embolism.

Nonpleuritic pain	6	3
Deep venous thrombosis with tachypnea	1	0.5

The most severe embolism, as assessed with pulmonary arteriography, occurred in patients with shock (mean score 26.3), syncope (mean score 25.8) and patients with uncomplicated embolism characterized by dyspnea (mean score 23.0). The severity was greater in each of these groups than in patients with pulmonary infarction characterized by hemoptysis (mean score 18.2) or pleuritic pain (mean score 20.4) ($p < 0.05$, one way analysis of variance).

Predisposing factors: These were deep venous thrombosis, immobilization, operation, stroke and malignancy, one of which occurred in 76 percent of patients. Among the female patients, 85 percent had these predisposing factors, or a recent pregnancy or were taking antiovulatory agents. Obesity (weight 15 percent or more greater than ideal weight)[17] was a possible predisposing factor in 3 percent of patients. However, in these patients obesity was accompanied by some other disease such as diabetes mellitus or gout; none of the patients in whom obesity was an apparent predisposing factor were otherwise perfectly healthy and not treated with antiovulatory agents. Many patients had more than one predisposing factor, the average being

TABLE V

P_2 = pulmonary component of second heart sound.

between one and two. A few patients (14 percent) had none of the commonly recognized predisposing factors. Specifically, 14 percent had no deep venous thrombosis, immobilization, operation, recent pregnancy, stroke, malignancy or obesity or were being treated with antiovulatory agents. However, only 4 percent of patients appeared to have been completely healthy before the embolism and were not taking oral contraceptive agents.

The distribution by sex was nearly equal; 57 percent were male and 43 percent were female. The ages were also equally distributed for the various syndromes of acute pulmonary embolism, with the exception of pulmonary infarction characterized by hemoptysis. The median age of the women in this group was 29.5 years, which was prominently lower than the age of men with hemoptysis (47.5 years) and of the women in the other syndrome groups.

Discussion

Although cardiac and pulmonary disease are well known predisposing factors for acute pulmonary embolism,[5] the histories of the patients in the Urokinase Pulmonary Embolism Trial and the Urokinase-Streptokinase Embolism Trial indicated that 65 percent of these patients were free of these conditions. The features of the history and physical examination in patients without preexisting cardiac or pulmonary disease are therefore relevant to the diagnosis of a large proportion of patients with acute pulmonary embolism. The information also may be applicable to the assessment of patients who have coexisting cardiac or pulmonary disease.

Advantages and limitations of study: A study such as this had advantages and disadvantages. The fortunate aspects are that a broad experience is made available through the data from these cooperative studies of thrombolytic agents. This is by far the largest group of patients with proved acute pulmonary embolism reported on whose diagnostic features were not confused by preexisting cardiac or pulmonary disease. The opportunity to identify the signs and symptoms in such a group, and particularly the opportunity to identify combinations of useful clinical features, is unique. Such specific information cannot be retrieved from the numerous reported studies.

A clear assessment of the limitations of this investigation is useful. There was no mechanism to determine the quality of the symptoms and signs enumerated. Thus, further details about important symptoms could not be determined. For example, we could identify dyspnea as the most frequent symptom. We could not determine if the patient had sudden and unexplained dyspnea, even though such as assessment would be of great value.[18]

In this study, data concerning the prevalence of predisposing factors should be considered in light of the source of the data. These data were obtained from a therapeutic trial. Several categories of patients were excluded such as those who had had an operation within 10 days before the onset of symptoms of pulmonary embolism. Such patients represent a large proportion of those who have acute pulmonary embolism. The predisposing factors enumerated are therefore biased by the exclusion of this group as well as other categories of patients. Because of these exclusions, it is possible that the prevalence of patients free of apparent predisposing factors may be exaggerated. However, it has been reported that pulmonary embolism occurs in previously healthy people.[19] Many of these otherwise healthy patients were obese, or had deep venous thrombosis, and some of the patients were pregnant.[19]

Role of electrocardiogram: The chest roentgenogram as well as the electrocardiogram (data we[20] previously reported on in about half of these patients) provide important data supplementing the signs and symptoms. In patients without preexisting cardiac or pulmonary disease, the electrocardiogram may be strongly supportive of the clinical diagnosis of acute

pulmonary embolism. The most frequent abnormality is a nonspecific change of the S-T segment or T wave that occurs in more than 40 percent of patients with massive or submassive acute pulmonary embolism.[20] Even minor changes of the S-T segment or T wave are supportive of the diagnosis, especially when these are new findings or clear rapidly after the event. A normal electrocardiogram is uncommon in acute pulmonary embolism and is found in only 6 percent of patients with massive pulmonary embolism and in 23 percent of those with submassive embolism.[20] Complete right bundle branch block, right axis deviation, an $S_1Q_3T_3$ pattern or P pulmonale occurs in approximately one third of patients with massive or submassive pulmonary embolism.[20] Left axis deviation is found as frequently as right axis deviation in acute pulmonary embolism and therefore does not exclude the diagnosis.[20]

Role of chest roentgenogram: The chest roentgenogram is strongly suggestive of pulmonary embolism if it is normal in a severely dyspneic patient.[18] A dome of the diaphragm may be elevated. A localized radiodensity may represent pulmonary infarction, and a small effusion often accompanies this event. Large pleural effusions are rare in pulmonary embolism and suggest another disease process.[18] The most common abnormalities in the plain chest roentgenogram are pleural effusion or infiltrate, each of which occurs in slightly more than half of the patients with acute pulmonary embolism; but some of these patients also had cardiac or pulmonary disease.[21] At least two of the following—pleural effusion, infiltrate, atelectasis or an elevated hemidiaphragm—were present in 44 percent of patients with acute pulmonary embolism.[21]

Diagnostic clinical manifestations: The identified clinical manifestations are, as a group, strongly suggestive of acute pulmonary embolism. Patients with acute pulmonary embolism who are free of dyspnea, tachypnea or deep venous thrombosis are rarely identified, and whether such patients exist is uncertain. A comparison of the signs and symptoms that we report in patients without preexisting cardiac or pulmonary disease and the signs and symptoms reported by others in such patients is shown in Table VI. The higher prevalence of circulatory collapse and the lower prevalence of hemoptysis and pleuritic pain in the patients reported by Sutton et al.[6] reflect the greater severity of the pulmonary embolism in their patients.

Implications: The importance of the history and physical examination relates to the selection of patients for pulmonary arteriography. We do not propose that a definitive diagnosis should be made on the basis of the history and physical examination. However, a carefully performed and properly interpreted history and physical examination should markedly reduce the frequency of negative pulmonary arteriograms, which has been reported to be as high as 73 percent at some institutions.[9] Certainly, a definitive diagnosis should be made in each instance, and this usually can be accomplished by scintillation scans. If invasive or thrombolytic therapy is contemplated, then pulmonary arteriography is required. However, the indiscriminate use of pulmonary arteriography can lead to morbidity and frequently to an uncertain diagnosis.[18] The history and physical examination are fundamental to the diagnosis of pulmonary embolism. The signs and symptoms of acute pulmonary embolism are not so elusive that a tentative diagnosis cannot be made or rejected. Greater reliance on the clinical manifestations will improve the selection of patients for pulmonary arteriography, and may decrease the reported high frequency of negative pulmonary arteriograms.

Bedside Recognition, Incidence and Clinical Course of Right Ventricular Infarction

GUILLERMO B. CINTRON, MD, FACC
EDGARDO HERNANDEZ, MD, FACC
ESTEBAN LINARES, MD, FACC
JUAN M. ARANDA, MD, FACC

San Juan, Puerto Rico

To evaluate the incidence, clinical characteristics and course of right ventricular infarction, 96 patients with an established diagnosis of acute myocardial infarction were evaluated during a 10 month study period. Of the 44 patients with acute inferior wall myocardial infarction, 16 had bedside evidence of right ventricular dysfunction. All had a positive Kussmaul's sign, and 12 had either a right ventricular third or fourth heart sound. Inspiratory elevation of right atrial and right ventricular end-diastolic pressures was documented in nine patients. Ventricular fibrillation developed in one patient and advanced atrioventricular block in three. All 16 patients survived and were alive 3 months after infarction. The hospital course and 3 month survival rate were not different from those of the usual patient with inferior wall infarction. Approximately one third of the patients with inferior wall myocardial infarction have bedside evidence of right ventricular infarction, which usually does not alter short-term prognosis.

Since the initial description of right ventricular infarction, the clinical syndrome has been recognized with increasing frequency. The clinical picture described by Cohn et al.[1] of acute inferior wall myocardial infarction with elevated systemic venous pressure, clear lungs, systemic hypotension and atrioventricular (A-V) block is well known. The diagnosis can be further documented with right heart catheterization or gated scintigraphy and technetium-99m pyrophosphate myocardial imaging.[2,3] The clinical incidence of right ventricular infarction has been estimated to vary between 3 and 8 percent of all cases of myocardial infarction,[4] whereas pathologic and radionuclide studies have found a 24 to 37 percent incidence rate of right ventricular involvement in patients with inferior myocardial infarction.[3,5] Most authors have emphasized the invasive diagnostic procedures and serious complications of right ventricular infarction. This study was undertaken to evaluate, in a prospective fashion, the bedside clinical diagnosis, incidence and course of right ventricular infarction.

Methods

Study patients: During a 10 month study period all 96 patients admitted to the Coronary Care Unit of the San Juan Veterans Administration Hospital, Puerto Rico with the diagnosis of acute myocardial infarction were screened by one of us. The diagnosis of myocardial infarction was established by the clinical picture plus the usual electrocardiographic and serum enzyme criteria (elevation of serum glutamic oxaloacetic transaminase, lactic dehydrogenase and creatine kinase). The site of infarction was determined with electrocardiographic criteria.[6] All patients were carefully examined for clinical signs of right ventricular dysfunction. Patients with acute inferior wall myocardial infarction and clinical evidence of new right ventricular dysfunction in the absence of pericardial disease, chronic pulmonary disease or chronic heart failure were considered to have right ventricular infarction.

Hemodynamic studies: Such studies were obtained in some patients as part of an on-going research protocol.[7] In the patients with clinical evidence of right

ventricular dysfunction who underwent hemodynamic studies, pressure tracings were obtained during continual expiration and inspiration in the right atrium, right ventricle and pulmonary artery. Pressures were measured with a Swan-Ganz catheter through a Statham P23-ID pressure transducer and recorded with an American Optical two channel recorder. The patients were maintained on a cardiology ward during the rest of their hospital stay.

Follow-up: Follow-up information 3 months after the myocardial infarction was obtained from the clinical chart, by telephone or by personal interview. In approximately half of the patients (random selection), postconvalescence exercise testing was done using the standard Bruce protocol 3 months after the myocardial infarction.

Results

Incidence: During the study period, 96 men were admitted with a documented diagnosis of acute myocardial infarction. Forty-seven had anterior myocardial infarction, 44 had inferior myocardial infarction and 4 had lateral and 1 posterior myocardial infarction (Fig. 1). Sixteen patients (16 percent) demonstrated new clinical evidence of right ventricular dysfunction and were considered to have right ventricular infarction. All of these patients had acute transmural inferior wall myocardial infarction. One third (36 percent) of all patients with inferior wall myocardial infarction had clinical evidence of right ventricular dysfunction.

Clinical and hemodynamic data: The mean age of the 16 patients with right ventricular infarction was 55 years (Table I). Only 2 of the 16 had evidence of prior myocardial infarction. Nine patients had isolated inferior wall myocardial infarction and four had inferolateral and three inferoposterior infarction. Four patients had marked elevation of the central venous pressure (greater than 10 cm H_2O) by clinical estimate. All 16 patients demonstrated a positive Kussmaul's sign with distension of the jugular veins during inspiration.

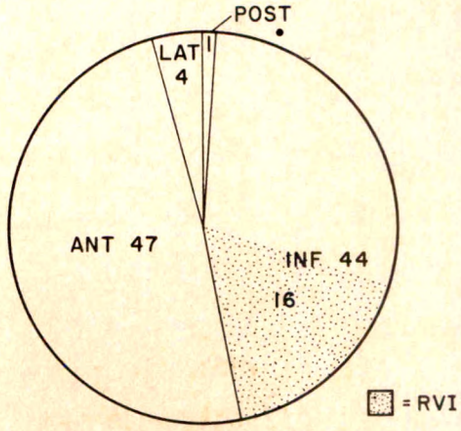

FIGURE 1. Site of acute myocardial infarction in 96 patients. **Shaded area** represents patients with acute right ventricular infarction (RVI). ANT = anterior; INF = inferior; LAT = lateral; POST = posterior.

Eleven patients had a right ventricular third heart sound and four had a right ventricular fourth heart sound. None of the patients had an audible murmur of tricuspid regurgitation. These clinical findings were present within 48 hours of admission to the coronary care unit and disappeared in all but two of the patients by the time of discharge from the hospital. Radiography was generally not helpful because only portable X-ray films were obtained; pulmonary congestion was observed in eight patients and cardiomegaly in seven.

Ten of the 16 patients with right ventricular infarction underwent right heart catheterization. Respiratory variation of right atrial and right ventricular pressures were recorded in nine patients. All nine patients demonstrated an inspiratory increase in mean right atrial pressure and in right ventricular end-diastolic pressure (Fig. 2). Mean expiratory right atrial and right ventricular end-diastolic pressure was 7.8 ± 1.2

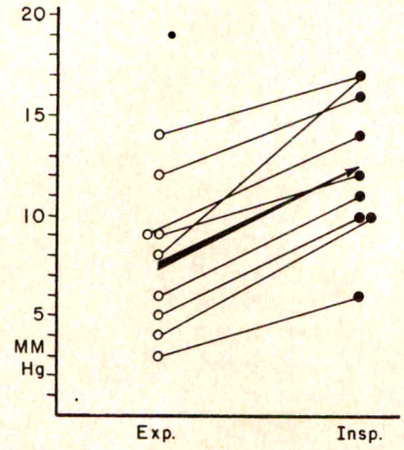

FIGURE 2. Inspiratory change in right atrial and right ventricular end-diastolic pressures in nine patients with right ventricular infarction. **Open circles** = pressure at expiration (Exp.); **closed circles** = pressure at inspiration (Insp.). **Heavy line with arrowhead** indicates mean value for the group.

mm Hg. Mean inspiratory right atrial and right ventricular end-diastolic pressure was 12.5 ± 1.2 mm Hg. The mean pulmonary arterial diastolic pressure in the group was 12.7 ± 1.1 mm Hg.

Clinical course: None of the patients exhibited clinical evidence of pericarditis, pericardial tamponade, shock or congestive heart failure during the hospital stay. Right bundle branch block developed in two patients, second degree A-V block in two and complete A-V block in one. No patient required a temporary pacemaker. Defibrillation was successful in one patient who manifested ventricular tachycardia and fibrillation. All patients survived the hospitalization and were alive 3 months after the acute myocardial infarction.

Seven patients underwent exercise testing 3 months after the myocardial infarction. The mean maximal work load achieved was 7.7 METS. This compares favorably with our previously reported value of 7 METS achieved by patients tested 12 weeks after uncomplicated convalescence from acute myocardial infarction.[8] We compared the clinical course of the 16 patients with acute right ventricular infarction with that of 14 randomly selected patients during the same study period who had had an acute inferior wall myocardial infarction without clinical evidence of right ventricular dysfunction. The incidence of complications, duration of hospitalization and 12 week survival rate were similar in both groups.

Discussion

The bedside diagnosis of right ventricular infarction has been based on the recognition of severe right ventricular dysfunction with resultant right-sided heart failure. The clinical recognition has thus been limited to cases in which right ventricular involvement has been very extensive. This may be the cause for the low reported incidence rate of clinical right ventricular infarction. Necropsy and radionuclide studies have identified a larger incidence of anatomic right ventricular infarction. This difference could be based on the fact that infarcts that involve a small amount of right ventricular muscle mass may not produce enough right ventricular dysfunction to become clinically apparent.

Response of right-sided pressures to inspiration (Kussmaul's sign): Experimental necrosis of the right ventricle has been proved to decrease the ability of the right ventricle to handle a volume load.[4] Increasing the systolic load of the right ventricle has also been proved to result in abnormal right ventricular end-diastolic pressure in patients with right coronary artery disease.[9] A maneuver that would stress the right ventricle may thus help uncover any subclinical dysfunction. The simplest bedside maneuver to stress the right ventricle is inspiration. Normally, during inspiration, there is an increase in the venous return to the right side of the heart. At the same time, pulmonary vascular impedance is decreased during inspiration, thus facilitating right ventricular emptying.[10] The inspiratory increase in venous return is so well handled by the healthy right ventricle that right ventricular end-diastolic pressure and right atrial pressure decrease. This physiologic response is altered in right ventricular infarction and may be the earliest bedside sign of right ventricular infarction. It is of interest that none of our patients with acute anterior myocardial infarction and left ventricular failure had a positive Kussmaul's sign.

Recently, Coma-Canella and Lopez-Sendon[11] also described the noncompliant nature of the right ventricle in patients with acute right ventricular infarction. This diastolic right ventricular dysfunction explains the right ventricular third and fourth heart sounds found in the majority of our patients. None of our 14 patients with inferior wall infarction and negative Kussmaul's sign exhibited a third or fourth heart sound even though four had a pulmonary wedge pressure greater than 12 mm Hg.

In some of our patients with a positive Kussmaul's sign associated with acute inferior wall myocardial infarction, right-sided hemodynamic studies were obtained. We documented elevation of the right ventricular end-diastolic pressure during inspiration. This pressure is transmitted to the right atrium and hence to the jugular venous pulse, giving the characteristic response of Kussmaul's sign. Most of our patients had a normal mean right atrial pressure, which probably reflects their minor degree of right ventricular dysfunction. None of our patients had clinical signs or symptoms of pericardial disease. Pericardial effusion was excluded by M mode echocardiography in six of the patients with right ventricular infarction. Lorell et al.[12] also emphasized this point of differential diagnosis of right ventricular infarction and pericardial disease.

Clinical course and prognosis: The clinical course of our patients with right ventricular infarction was not different from the course of a random group of patients with acute inferior wall myocardial infarction without signs of right ventricular infarction. The 3 month survival rate was 100 percent in both groups. Performance

of the patients with right ventricular infarction on exercise testing 3 months after infarction was comparable with that of our usual patient with an uncomplicated myocardial infarction. This finding indicates that right ventricular infarction may not necessarily carry a bad prognosis, in contrast to data from other studies[1,2,4] showing a large incidence of shock, A-V block and death in right ventricular infarction. This difference may again reflect the rather extensive myocardial damage needed to produce severe right ventricular failure. It appears that clinically right ventricular infarction presents a wide spectrum from a rather benign, uncomplicated entity to a catastrophic event with A-V block, shock and even death. Appropriate therapy in patients with acute right ventricular infarction and systemic hypoperfusion secondary to inadequate left ventricular filling pressure usually produces a satisfactory result.

Clinical implications: Anatomic right ventricular infarction is seen in approximately one third of patients with acute inferior myocardial infarction. Careful bedside physical diagnosis can identify these patients by demonstrating a positive Kussmaul's sign plus a right ventricular third or fourth heart sound. Generally this is a benign condition. However, in some patients such severe right ventricular failure may develop that the resultant decrease in left heart venous return will decrease left ventricular output and cause systemic hypoperfusion. In these cases, expansion of intravascular volume and use of inotropic agents usually produce hemodynamic improvement. Therapeutic interventions that decrease right-sided venous return should be carefully monitored in patients with right ventricular infarction because these interventions will compromise right ventricular output with subsequent hemodynamic deterioration.[13]

Unstable Angina Pectoris of New Onset: A Prospective Clinical and Arteriographic Study of 75 Patients

MARK F. VICTOR, MD
MARIELL J. LIKOFF, MD,
GARY S. MINTZ; MD, FACC
WILLIAM LIKOFF, MD, FACC

Philadelphia, Pennsylvania

Seventy-five patients with unstable angina pectoris of new onset (defined as of less than 90 days' duration) were prospectively evaluated in terms of clinical and arteriographic findings. In all patients the angina was considered unstable in terms of ease of provocation of anginal attacks and frequency of occurrence of attacks. Sixty patients had significant obstruction of at least one coronary artery, whereas 15 had insignificant disease (less than 70 percent arterial narrowing) or normal coronary arteries. Thirty-one patients (52 percent) had single vessel coronary disease, 11 (18 percent) had double vessel disease and 9 (15 percent) had triple vessel disease; the remaining 9 (15 percent) had left main coronary artery disease, either alone or in association with other vessel involvement. Of the 31 patients with single vessel disease, 24 (77 percent) had stenosis of the left anterior descending artery. The patients with single vessel disease did not differ from the patients with multivessel involvement with respect to risk factors or clinical presentation.

It is concluded that patients with unstable angina of new onset have an unusually large incidence of single vessel coronary artery disease predominantly involving the left anterior descending coronary artery. Thus, these patients constitute a unique subset of patients with angina pectoris.

Unstable angina pectoris is an alarming clinical syndrome describing an accelerated pattern of ischemic chest pain, variably leading to myocardial infarction and death. Evaluation of the syndrome has been complicated by conflicting reports on the short- and long-term prognosis of affected patients.[1–12] Chahine[13] suggested that defined subgroups within the unstable angina population accounted for the variable prognoses.

One of the proposed subsets of unstable angina is that of angina of new onset or angina de novo. This clinical syndrome can be defined as the development of angina pectoris within 60 to 90 days in a patient with no previous angina. Because patients with new onset angina have so often been included in the global category of unstable angina, their particular clinical characteristics, as well as arteriographic anatomy, have not been stressed. Accordingly, this investigation was designed as a prospective study to identify the clinical manifestations and arteriographic anatomy of this subgroup.

Methods

Study patients: All patients selected for study were admitted with angina de novo to Hahnemann Medical College and Hospital between January 1977 and December 1979 and subsequently underwent cardiac catheterization within 3 months of the onset of their chest pain syndrome. A patient was included in the study group after a cardiologist other than the investigators had decided to submit the patient for cardiac catheterization. Thus, patients with angina de novo who did not undergo cardiac catheterization were excluded.

Seventy-five patients (61 men and 14 women) fulfilled the criteria for inclusion into the study. On the basis of the variables of frequency, severity, and ease of

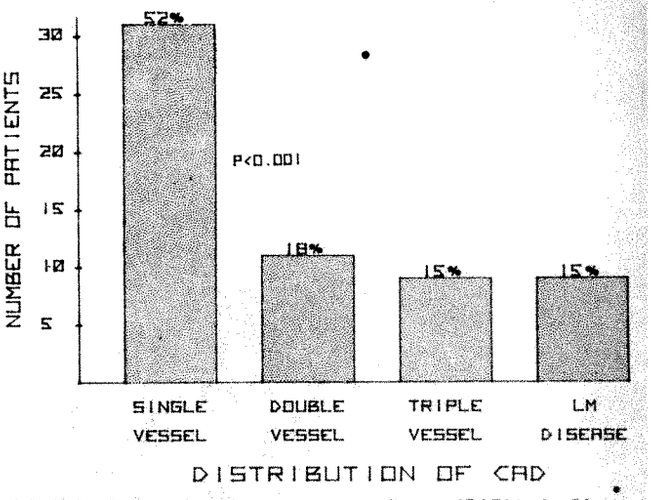

FIGURE 2. Distribution of coronary artery disease (CAD) in the 60 patients with significant obstruction. The **bars** indicate the frequency of single vessel, double vessel, triple vessel and left main (LM) coronary artery disease with percent of the group noted above.

precipitation of angina, all 75 patients were subsequently judged by us to have unstable angina, that is, to have rapidly progressive angina (type IC unstable angina using Chahine's definition[13]).

Patients with any clinical or electrocardiographic evidence of previous myocardial infarction or angina of more than 3 months' duration were excluded from the study. Similarly, patients were excluded if there was any evidence of recent infarction as diagnosed by elevation of serum creatine kinase, MB isoenzyme levels. Patients with valvular or congenital heart disease were not included in the study. All clinical histories were taken and angiographic studies reviewed by one of us in addition to the patients' own physician. All patients were entered into the study prospectively.

Risk factors: Each patient was questioned as to the presence or absence of the standard coronary risk factors. A patient was considered to be diabetic if he or she was taking insulin or an oral hypoglycemic agent or had a positive glucose tolerance test. A patient was labeled a smoker if he had at least a 20 pack-year history of cigarette smoking and had last smoked within the past 5 years. Similarly, hypertension, known hyperlipidemia and a family history of premature coronary disease were each listed as a risk factor.

Cardiac catheterization: Selective coronary arteriography was performed in nearly all patients by the Judkins technique, although a few patients with severe peripheral vascular disease underwent brachial arteriotomy using the Sones technique. The studies were performed with either a Phillips 6 inch (15.24 cm) image intensifier with videotape playback capacity or a Siemens 7.5 inch (19.05 cm) image intensifier also with video playback. The routine studies included left ventriculography in the right anterior oblique projection as well as selective left and right coronary arteriography. Views were obtained in the standard right and left anterior oblique projections as well as lateral and various sagittal oblique views so as to maximize diagnostic accuracy. The films were read by one of four arteriographers in addition to at least one investigator.

A hemodynamically significant obstruction of the coronary arteries was considered to be greater than 70 percent narrowing of luminal diameter except for the left main coronary artery where a 50 percent obstructing lesion was considered significant. Disease limited to a diagonal branch of the left anterior descending artery or a secondary marginal branch of the left circumflex artery was considered insignificant (this was present in only 1 patient). Thus, the number of vessels involved was assessed with disease of the left main coronary artery considered two vessel disease for statistical purposes. Patients with insignificant disease (less than 70 percent obstruction) of one, two or even three vessels were considered, for subgroup analysis, to have insignificant disease. In patients found to have normal coronary arteries, no maneuver to elicit coronary spasm was performed. Angiographic ventricular ejection fraction was calculated for each patient in whom a suitable end-diastolic and end-systolic frame could be measured using the area-length method.

Statistical analysis was performed using linear regression and chi-square tests.

Results

Insignificant or no coronary artery disease: Of the 75 patients studied, 60 had significant coronary artery disease. Fifteen patients had either insignificant coronary disease or entirely normal coronary arteries and were categorized together as the normal group. Of these 15, 4 patients (27 percent) had mitral valve prolapse demonstrated by ventriculography or echocardiography, or both (Fig. 1).

Significant coronary artery disease (Fig. 2): Analysis of the 60 patients with significant coronary artery disease revealed that 31 (52 percent) had single vessel disease; 11 (18 percent) had double vessel disease, 9 (15 percent) had triple vessel disease and 9 (15 percent) had disease of the left main coronary artery either alone (3 patients) or in association with other vessel involvement (6 patients). The frequency of single vessel disease differed significantly ($p < 0.001$) from that of double or triple vessel disease.

Single vessel disease: The distribution of coronary vessel involvement in the 31 patients with single vessel disease is shown in Figure 3. The incidence of disease isolated to the left anterior descending coronary artery was high. Specifically, 24 of the 31 patients (77 percent) had disease of the left anterior descending coronary artery, in contrast to 3 (10 percent) who had isolated left

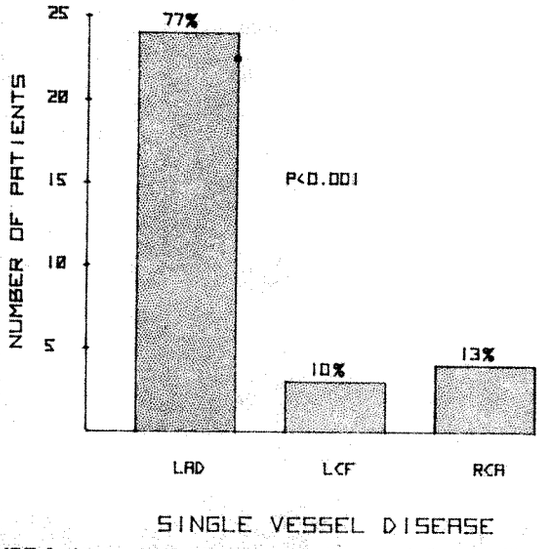

FIGURE 3. Anatomic distribution of single vessel disease. The **bars** show the percent of patients with isolated disease of the left anterior descending (LAD), left circumflex (LCF) or right coronary artery (RCA).

circumflex artery disease and 4 (13 percent) who had isolated right coronary artery disease. These values achieved statistical significance at a level of $p < 0.001$.

Degree of coronary obstruction: The coronary arterial luminal compromise in these patients was severe. Among the nine patients with involvement of the left main coronary artery, one had a 100 percent occlusion, and the mean degree of narrowing of this artery was 73 percent. Eight patients had 100 percent obstruction of the left anterior descending artery, and the mean degree of narrowing for all patients with disease of this artery was 89 percent. Similarly, 12 patients had 100 percent obstruction of the right coronary artery, and the mean degree of narrowing for all patients with disease of this artery was 92 percent. Two patients had 100 percent occlusion of the left circumflex artery, and the mean degree of narrowing of this artery was 82 percent. Of the 31 patients with significant coronary disease limited to a single vessel, that single vessel was narrowed by a mean of 91 percent.

The mean global left ventricular ejection fraction for the entire group of patients was 62 percent. For the patients with single vessel disease it was 65 percent.

Evaluation of risk factors: The total patient population was analyzed for the presence of five risk factors for coronary artery disease: smoking, hypertension, hyperlipidemia, family history of premature coronary disease, and diabetes mellitus (Fig. 4). It was not possible to separate the patients with single or multivessel coronary artery disease or disease affecting the left main coronary artery on the basis of any combination of risk factors. No correlation with any comparison of risk factors and coronary arterial anatomy could be found.

The peak incidence of single vessel disease occurred in the 5th decade (Fig. 5). There was no relation between the patients' age and the number of coronary vessels with significant obstruction.

Discussion

Not every patient with coronary heart disease initially presents with angina pectoris. In the Framingham study, only 37 percent of men and 65 percent of women had angina as the first manifestation of coronary disease.[11] The remainder presented with myocardial infarction or sudden death. These statistics may be colored by the fact that patients with rare, intermittent episodes of angina may not consult a physician about the symptom. In a population study conducted by Fulton et al.,[12] half the patients who had a myocardial infarction had had prior episodes of either new or

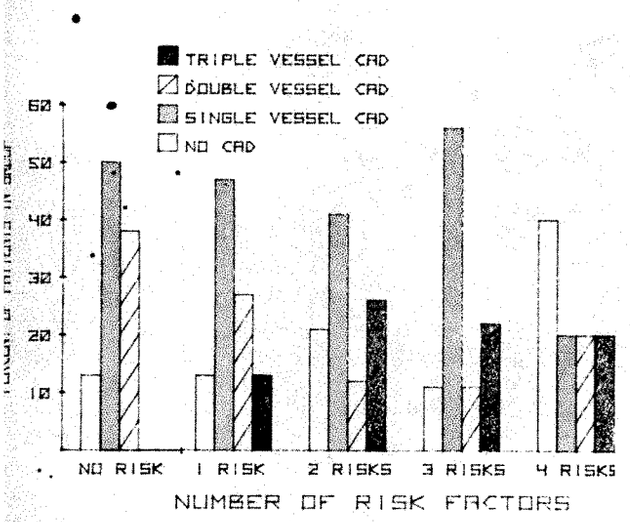

FIGURE 4. Risk factor analysis of patients with angina of new onset. The **bars** show the distribution of the patients according to their coronary anatomy versus the number of cardiac risk factors. (There was no statistical correlation.) CAD = coronary artery disease.

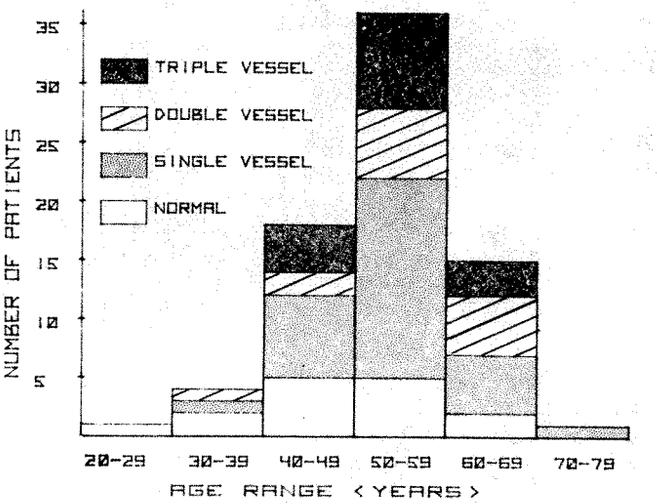

FIGURE 5. Age distribution of patients with angina of new onset. The incidence of single, double and triple coronary artery disease or no or insignificant coronary artery disease is displayed according to the patients' age by decade.

worsening angina but failed to consult a physician. Solomon et al.[14] reviewed prospectively the historical data of 100 patients admitted to the coronary care unit with myocardial infarction; 65 percent of these patients reported prodromal symptoms, mainly chest pain, within 2 months to 12 hours of infarction.

Given these facts, it would seem intuitive that physicians have long regarded rapidly progressive or unstable angina as a harbinger of myocardial infarction. Nevertheless, the population presenting with unstable angina has been difficult to define. More difficult still has been our ability to predict the eventual outcome of these patients. Thus, several investigators[1,13] have suggested analysis of the various subgroups that combine to form the population with unstable angina. In the patients with angina of recent onset constituting this report, the angina was considered unstable in all because of the increasing ease with which it was precipitated and the frequency and severity of the attacks. Indeed, it was the progressive worsening of the clinical condition that dictated the coronary arteriography. These 75 patients, therefore, represent the subgroup of patients with unstable angina de novo.

Frequency of single vessel coronary disease in new onset angina: Comparable reports of the angiographic anatomy of patients with unstable angina of new onset must be extracted from surveys of subjects classified as having unstable angina, independent of duration. One of the first clinical studies incorporating arteriography in the study of unstable angina was performed by Scanlon et al.[2] in 1973. They studied a group of 79 patients with unstable angina; 15 (19 percent) of the 79 had normal coronary arteries, 18 (23 percent) had single vessel disease, 14 (18 percent) had double vessel disease and 32 (40 percent) had disease of three or more vessels. Several later studies[3,7,8,10] confirmed that two or three vessel coronary disease could be found in more than two thirds of patients with unstable angina.

The prevalence of coronary arterial involvement changes as the duration and type of angina are categorized. Proudfit et al.[15] reported a 32 percent incidence rate of significant single vessel obstruction in patients with functional class I, II or III angina of less than 1 year's duration. Furthermore, when patients with functional class IV angina of less than 1 year's duration were examined, an approximate 40 percent incidence rate of single vessel disease was found. Likewise, in a later publication, the same group[16] described 74 patients, in a series of 601, with angina of all classes for less than 1 year. Of those 74 patients, 47 percent had significant single vessel obstruction. On analysis limited to the 21 patients with class III and IV angina, 38 percent were found to have single vessel disease. Thus, regardless of the severity of angina, the duration of the chest pain syndrome appears to be directly related to the number of coronary vessels obstructed.

These conclusions are further substantiated by the work of Lawson et al.[17] They reported on 41 patients admitted to the hospital with angina at rest whose pain persisted with hospitalization. None of the patients had an acute myocardial infarction and all underwent subsequent cardiac catheterization and coronary bypass surgery. Sixteen of the 41 patients had angina de nov as defined in our study, and 8 (50 percent) of the 16 r quired only a single bypass graft, usually to the le anterior descending artery, whereas a single graft wa performed in only 8 percent of patients with lon standing angina. In addition, when compared with p tients with long-term angina, subjects with corona insufficiency of new onset had markedly fewer collater vessels, which may have accounted for the rapid ons of symptoms.

In contrast, Douglas and King[18] found single vess disease in only 22 percent of 159 men with initial ons angina. However, it is not clear how many of these p tients had had a prior myocardial infarction or how lo the duration of the pain had been. In 22 women wi initial onset angina, cardiac catheterization reveale significant single vessel obstruction in 33 percent. Aga the characteristics of the subgroup alter the arteri graphic findings.

Our study clearly documents that the subset of p tients with unstable angina de novo is distinguished b a high percentage of persons with single vessel corona artery disease. The coronary lesions are characterist cally proximal and severely obstructed. In this serie the coronary artery most commonly involved was t left anterior descending artery.

Analysis of multiple risk factors: Our study faile to disclose any one risk factor or combination of facto that would help predict coronary arterial anatomy. addition, neither age nor sex was helpful as a predicti variable, a finding in keeping with the data of oth investigators.[18]

Ventricular function: The mean value for le ventricular ejection fraction in our patients was percent. This normal value is not unexpected becau patients with previous infarction were excluded fro the study. The routine discovery of normal left ve tricular function underscores the possibility of inte vention prior to myocardial damage.

Prognostic implications: Given the unexpected large incidence of single vessel disease in this subset patients with unstable angina, it is worthwhile to e amine the possible implications of these results on t prognosis for the population as a whole. For exampl Krauss et al.[19] studied 100 patients with coronary i sufficiency and found (1) an in-hospital mortality ra of 1 percent, and a 1 year mortality of 15 percent; (2) in-hospital infarction rate of 6 percent, with a 1 ye infarction rate of 20 percent. Gazes et al.[20] followed 140 patients with unstable angina, 27 of whom had a gina of new onset. The overall 1 year mortality rate the group was 18 percent and, thereafter, the annu attrition rate was 4 to 5 percent. However, there we no deaths and only one infarction in the first 3 mont of follow-up of patients with unstable angina of ne onset.

In contrast, Fulton et al.[12] examined 167 patients, (53 percent) of whom had unstable angina of rece onset. They found that 17 (10 percent) of the 167 h an acute coronary event (myocardial infarction sudden death) within 4 weeks and an additional ni events within the next 2 months. Similarly, Duncan

.[21] followed up 251 men, 129 (50 percent) of whom had nstable angina de novo. Twenty-eight (11 percent) of ıe 251 had a coronary event within 6 weeks and an ldditional six events occurred within the next 6 weeks. ı the latter two studies of unstable angina, the large roportion of patients with new onset angina may in art explain the high incidence rate of early coronary ents.

The distinct natural history of early onset angina has een emphasized by Short and Stowers.[22] They ana-zed the histories of patients from the onset of angina ıtil death or myocardial infarction intervened. They und a 4 percent incidence rate of coronary events ithin the 1st week after the onset of angina, a 2 per-nt/week incidence rate of events during the next 3 eeks, and a 0.6 percent/week incidence rate during the xt 2 months. Patients with an "abrupt onset" of an-na, in contrast to those with an "insidious onset," had startling 18 percent incidence rate of coronary events thin the 1st week. Clearly, then, any analysis of a pulation with unstable angina must include a detailed ronicle of the time course of the chest pain syndrome. ognosis seems to depend not only on the number of ronary vessels involved, but on the rapidity with ıich symptoms develop.

Clinical implications: This study identifies a subset patients within the category of unstable angina, namely, those with angina of recent onset or angina de novo. This group differs from the category as a whole, in that the coronary arterial lesions in more than 50 percent of the subjects may involve only a single vessel. Furthermore, the disease is apt to be proximal and severely obstructive. The desirability of performing early coronary arteriography in patients with unstable angina of recent onset should be stressed because the vascular lesions may be amenable to angioplasty[23] or aortocoronary bypass surgery.

Valid questions still exist as to the clinical pattern of these patients in terms of their propensity for early coronary events, particularly myocardial infarction. In addition, more information is needed about these patients compared with patients with angina de novo that is not unstable. Studies on the medical and surgical management of unstable angina will have to evaluate each clinical subset within an overall study group. It appears clear that the coronary anatomy and left ventricular function may vary widely depending on the clinical subset in question, thus influencing prognosis. This is particularly true of those patients with angina of new onset.

Prognostic Importance of Anginal Symptoms in Angiographically Defined Coronary Artery Disease

PETER F. COHN, MD, FACC
PHILLIP HARRIS, MB, DPhil, FACC
WILLIAM H. BARRY, MD, FACC
ROBERT A. ROSATI, MD
PAUL ROSENBAUM, PhD
CHRISTINE WATERNAUX, PhD

Durham, North Carolina

To evaluate the prognostic importance of anginal symptoms, 44 patients with angiographically defined coronary artery disease and no anginal symptoms at time of cardiac catheterization were selected from the Duke Harvard Collaborative Data Bank. They were "matched" with 127 symptomatic patients in the Data Bank who had similar coronary anatomy and ventricular function. Follow-up data indicated that the patients without anginal symptoms had a significantly better prognosis over a 7 year period than did those with symptoms: Annual mortality in the asymptomatic group was 2.7 percent compared with 5.4 percent in the group with angina ($p < 0.05$). Although the patient population was a highly selective one and the matching categories were relatively broad, these results suggest that the presence of anginal symptoms may be an important independent correlate of prognosis in patients with coronary artery disease. The absence of angina did not preclude the presence of multivessel disease and did not necessarily imply a benign prognosis, because the yearly mortality rate was nearly 5 percent in the subgroup of asymptomatic patients with three vessel disease.

Despite the large number of studies on the natural history of angiographically defined coronary artery disease, it is still not clear whether the absence of anginal symptoms (chest pain or its usual equivalents in a given patient) is of prognostic significance when symptomatic and asymptomatic persons with similar coronary anatomy and ventricular function are compared. Two approaches are possible in obtaining such data. One approach involves a prospective evaluation of patients with and without symptoms who have undergone coronary arteriography. A second, retrospective, approach compares prognosis by using a data bank that matches patients with respect to selected variables. This data bank type of retrospective analysis for patients with coronary artery disease was introduced at Duke University Medical Center,[1,2] and has also been utilized at the University of Washington.[3]

In this study, we used the Duke-Harvard Collaborative Coronary Artery Disease Data Bank to compare the subsequent survival of patients with and without anginal symptoms at time of coronary arteriography. (Because of the small number of asymptomatic patients treated surgically, only nonsurgically treated patients were considered in this report.) The asymptomatic group included apparently totally asymptomatic persons as well as patients who had been symptom-free after a myocardial infarction. Each of the patients in the asymptomatic group was matched by computer with one to three similar patients with anginal symptoms at the time of coronary arteriography.

Methods

The coronary artery disease data bank: The Coronary Artery Disease Data Bank was established at the Duke University Medical Center in 1969. Specific baseline information concerning patients' history, physical examination, chest

roentgenogram, resting and exercise electrocardiograms and cardiac catheterization findings were acquired prospectively and stored in a computerized system that has previously been described in detail.[1,2] In 1976, the Peter Bent Brigham Hospital (with the Harvard Medical School and Harvard School of Public Health) began its own data bank as part of a joint effort with Duke. The patients selected for the present study are drawn from the Duke-Harvard Collaborative Data Bank.

Selection criteria for patients: Because the purpose of the study was specifically to evaluate the prognostic importance of anginal symptoms, patients with signs or symptoms of congestive heart failure were excluded from consideration, as were patients presenting with severe ventricular arrhythmias. A total of 44 nonsurgically treated patients who were free of anginal symptoms at the time of cardiac catheterization and had at least 75 percent stenosis of luminal diameter of one or more major coronary arteries were selected for the asymptomatic group. They constituted all such patients in the data bank, and were each individually matched with up to three similar nonsurgically treated patients with anginal symptoms. Thirty-nine of the 44 asymptomatic patients were drawn from the Duke coronary artery disease data bank, and five from the Peter Bent Brigham Hospital coronary artery disease data bank.

The symptomatic group totaled 127 patients. These patients were selected for medical rather than surgical therapy, on the recommendations of their individual physicians. Whether this selection process may have biased the results of the study are commented on at length in the Discussion section.) One hundred seventeen of the 127 symptomatic patients were drawn from the Duke experience, and the remaining 10 from the Peter Bent Brigham experience. The remainder of this section discusses aspects of the matching.

Five variables that reflected coronary anatomy and ventricular function were selected for matching: (1) the number of major coronary arteries with at least 75 percent stenosis (one, two or three); (2) left ventricular contraction pattern (because not all patients had volumetric analyses, qualitative measurements were used: normal, abnormal but not diffusely abnormal, or diffusely abnormal); (3) arteriovenous oxygen difference (3 to 4, 4 to 5, 5 to 6, 6 to 7, or greater than 7 volumes percent); (4) left ventricular end-diastolic pressure (0 to 10, 10 to 20, 20 to 30, or greater than 30 mm Hg); (5) number of prior myocardial infarctions (0, 1, 2, 3, or more). All patients were exactly matched for variables 1 and 2. For the other variables, a nearest available match was obtained using a version of the nearest available matching algorithm.[4] If several matches were of equal quality, then the match with the nearest year of catheterization to the asymptomatic patients was used. All 39 asymptomatic Duke patients were matched with 3 symptomatic Duke patients to ensure a large enough data base for comparative purposes. The smaller size of the Harvard data bank did not always permit this 3:1 ratio. Thus, only two of the five asymptomatic patients were matched with three symptomatic patients, one asymptomatic patient was matched with two symptomatic patients, and the remaining two asymptomatic patients could each only be matched with one asymptomatic patient. Because the experiences of both institutions were combined for the life table approach, this slight imbalance had no effect on the statistics defined later and had negligible effects on the resulting survival curves.

To ensure that the results of the survival analysis were not influenced by descriptors that were not selected to be matched by the computer, the asymptomatic and symptomatic patients were also compared for frequency of several other variables. These included prevalence of left main coronary arterial stenosis, left anterior descending arterial stenosis, mean age, prevalence of male sex, prevalence of diabetes mellitus and hypertension, frequency of anterior myocardial infarction and frequency of positive exercise tests. Other factors considered were month and year of entry into the study and time from myocardial infarction (where applicable) to entry in the study.

Statistical analysis: The commonly used Mantel test[5] for comparing stratified life tables was employed in this study. The test, a particular case of the Cox proportional hazards model,[6] is closely related to work by Mantel and Haenszel[7] and Cox[8]; it is described in detail in the Appendix.

The relatively small number of patients in the subgroups with one, two and three vessel disease did not permit meaningful prognostic comparisons. Based on Miettinen's formula 5.5 for a two-tailed 0.5 level test,[9] the probability of detecting a 5 percent difference in annual mortality with the entire sample was approximately 90 percent, but in a subgroup of half the sample, this probability fell to approximately 66 percent and with a subgroup one third of the sample, the probability was approximately 50 percent.

The chi-square test was used to compare the frequency of various clinical variables listed in Table I, with the exception of mean age, which was compared with use of an unpaired *t* test. The unpaired *t* test was also used to compare time from infarction to entry in the study.

TABLE I

Clinical and Angiographic Findings in Study Patients With and Without Anginal Symptoms

	Without Anginal Symptoms (n = 44)	With Anginal Symptoms (n = 127)
Mean age	47.6	49.0
Male sex	41 (93%)	107 (84%)
Diabetes	2 (4%)	8 (6%)
Hypertension	13 (29%)	27 (21%)
Diagnostic Q waves in electrocardiogram	23 (53%)	76 (60%)
Positive exercise test	17/31 (55%)	48/96 (50%)
Two vessel disease	13 (30%)	38 (30%)
Three vessel disease	18 (40%)	51 (40%)
Left main coronary arterial stenosis	0	0
Left anterior descending arterial stenosis	36 (82%)	91 (72%)
Totally occluded vessels	12 (27%)	34 (27%)
Abnormal left ventricular contraction pattern	32 (73%)	95 (75%)
Left ventricular end-diastolic pressure > 18 mm Hg	8 (18%)	18 (14%)
Arteriovenous oxygen difference > 5.5 volumes percent	9 (21%)	23 (18%)

Results

Clinical and angiographic findings in the asymptomatic patients: The major reason for cardiac catheterization in the 44 asymptomatic patients was prior myocardial infarction (32 patients). Thirty of these 32 patients were pain-free for at least 2 months before the catheterization. Nineteen of the 32 had treadmill exercise tests; 7 tests were positive by electrocardiographic criteria (1 mm or greater S-T segment depression), al-

though the test did not induce angina; the remaining 12 tests were negative or nondiagnostic (no S-T segment depression and less than 85 percent of predicted heart rate achieved). The other major reason for cardiac catheterization was a positive exercise test (10 patients); the remaining 2 patients had an abnormal resting electrocardiogram. Only 3 of the 44 patients were taking cardiac medications (propranolol by 2 and propranolol and nitrates by another). These three patients had had a prior myocardial infarction and, although asymptomatic for at least several weeks after the infarction, were given these medications for prophylactic reasons by their physicians.

Table I lists other relevant clinical and angiographic findings in this group. The mean age was just under 50 years; men predominated; diabetes mellitus was uncommon; more than half the patients undergoing exercise tests had an ischemic response; stenosis of the left anterior descending artery was very common, but there were no patients with stenosis of the left main coronary artery; left ventricular asynergy was also common. The median time of entry was January 1974 for the symptomatic group and March 1975 for the asymptomatic group. No patients entered the study before 1970. The time from infarction to entry in the study (where applicable) was 27.8 months ± 6.4 (mean ± standard error of the mean) in the asymptomatic group and 33.4 months ± 4.5 in the symptomatic group (p = not significant [NS]).

Clinical and angiographic findings in the symptomatic patients: The 127 patients in the symptomatic group were all taking propranolol or nitrates, or both. Although the degree of symptoms varied considerably, less than 10 percent were considered as having unstable angina at time of catheterization. When the relevant clinical and angiographic findings in this group of patients were compared with those of the asymptomatic group, no significant differences were observed (Table I).

Prognosis in patients with and without anginal symptoms: Table II depicts the 7 year comparative survival statistics for the total group of 171 patients with and without symptoms. Only 2 of the 31 deaths were due

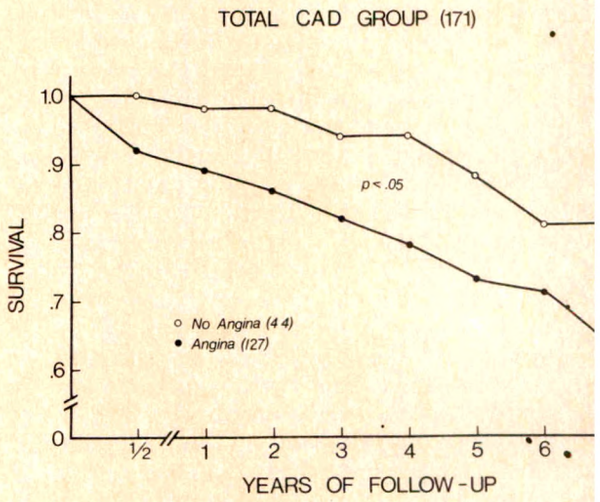

FIGURE 1. Survival curves (based on data in Table II) for 44 patie without anginal symptoms and 127 matched patients with angi symptoms.

to noncardiac causes. Figure 1 depicts the resulti survival curves. The mean follow-up time was 3.9 yea in the symptomatic group and 3.6 years in the asym tomatic group (p = NS).

There was an 81 percent survival rate for the to asymptomatic group at 7 years (yearly mortality percent) compared with a 62 percent survival rate the symptomatic group (yearly mortality 5.4 percen The worst prognosis, as expected, was in the subgro with three vessel disease (4.7 versus 8.7 percent in t symptomatic group). The survival curve for the over group was significantly better in the asymptomatic th in the symptomatic patients (p <0.05*).

Two of the four patients in the asymptomatic gro who died had anginal symptoms at least 6 months b fore their death (all four were in the subgroup with pr myocardial infarction). In general, development of a

* Mantel-Haenszel statistic 4.43 on 1 degree of freedom (t tailed).

nal symptoms was uncommon in this group. At the 6 onth follow-up period, 17 percent reported symptoms, ıd by 4 years, this figure had risen to only 30 percent. ıly 1 patient in this group was eventually referred for yocardial revascularization compared with 14 patients the symptomatic group. For purposes of this study, e last follow-up period was the one immediately eceding surgery.

Discussion

Our results suggest that patients who are not taking rdiac medications and are free of anginal symptoms the time of coronary arteriography have a better ognosis than do symptomatic patients with similar nical, angiographic and hemodynamic findings. The udy cannot be construed as a true reflection of the ıtural history of asymptomatic coronary artery dis-se, however, because nearly three fourths of the study oup had sustained a prior myocardial infarction. ırthermore, we defined asymptomatic coronary artery sease on the basis of angina alone and patients with her manifestations of myocardial ischemia (such as rhythmias and congestive heart failure) were ex-ıded. Nevertheless, the study does provide important ta in an area noted for its paucity of studies. Except r a preliminary report of a study in progress at the ıtional Institutes of Health,[10] which also suggests a tter prognosis for asymptomatic patients (2 percent nual mortality rate, similar to the 2.7 percent rate in e present study), there are virtually no data available the prognostic importance of anginal symptoms in giographically defined coronary artery disease.

Prognosis in patients with silent myocardial hemia: It is important to know the effects of anginal mptoms on prognosis because asymptomatic patients undergoing coronary arteriography with increasing quency. Whether asymptomatic patients *should* be erred for coronary arteriography is irrelevant for the rposes of this study, although it is an acknowledged ıtroversial decision. The most numerous of these tients are those with prior myocardial infarctions, as lected in the present study (32 of 44 patients). Less mmon are apparently totally asymptomatic persons o are referred for coronary arteriography, usually on basis of a markedly positive exercise test.[11] (Many the patients with a prior myocardial infarction also ve a positive exercise test.) Physicians are naturally ed with the dilemma of what treatment, if any, to er these persons. One could hypothesize that silent ocardial ischemia may be related to a defective an-al warning system and these patients may even be increased risk for myocardial infarction or sudden ıth; in other words, these patients have no angina to p them from the activity that is inducing the isch-ia.[12] This is an attractive theory, but it remains un-ven, although there are data indicating that patients h silent myocardial ischemia after myocardial in-ction—as evidenced by exercise-induced S-T seg-nt depression without symptoms—have the *same* 1 r mortality rate as patients with both S-T segment depression and test-induced angina.[13] Only 17 patients without angina in this study had a positive exercise test by electrocardiographic criteria and could be considered to have silent myocardial ischemia. This number was too small for meaningful prognostic comparisons using our data bank system, and thus we could not adequately address the issue of prognosis in silent myocardial ischemia. Large numbers of asymptomatic patients with a positive exercise test (or other evidence of myocardial ischemia such as an abnormal exercise radionuclide ventriculogram) must be followed up for at least a 5 year period to provide meaningful data concerning this important subset of asymptomatic patients with coronary artery disease.

Limitations of the study: In addition to insufficient data on the subject of silent myocardial ischemia, there are other limitations to our study that must be considered in interpreting its conclusions: (1) Some of the matching categories were relatively broad. For example, quantitative ventriculographic analyses of global and regional function were not available in many of the patients, and thus assessment of ventricular function relied on commonly accepted but qualitative indexes. In addition, the only quantitative coronary arteriographic matching criterion was the presence or absence of 75 percent or greater stenosis of luminal diameter. (2) Because the spectrum of anginal pain in the symptomatic group varied considerably from mild to severe, it is probable that within the overall group are subgroups of patients with different prognoses. This is not necessarily an undesirable feature, because having such a varied group yields a more representative "mix" of symptomatic patients. (3) Finally, could bias in the decision to treat these symptomatic patients medically have influenced the results of the study? These patients were treated medically, rather than surgically, because of the preferences of their referring physicians. The motivation of these decisions is not always readily apparent from material in the Data Bank. Therefore, it is possible that in some of these patients the degree of coronary disease or myocardial dysfunction, or both, was deemed too diffuse or severe for surgery and that despite attempts to match these factors in the asymptomatic group, the survival curves were skewed in favor of the asymptomatic patients.

Although we cannot fully exclude such bias because of the relatively broad stratifying categories employed in this study, we think the effect has been minimal for the following reasons. The annual mortality rate in medically treated but "good risk" patients is reliably estimated at 4 percent,[14] whereas "poor risk" medically treated patients have a 7.6 percent yearly mortality rate[15] and patient groups with a mixture of the two have a 5.5 percent yearly mortality rate.[16] Since our yearly mortality rate (5.7 percent) was similar to this latter figure, we believe that our symptomatic group represents a fair mix of "good" and "poor risk" medically treated patients.

Clinical implications: Despite the highly selective nature of the patient population, the relatively broad

natching categories, the absence of data on silent nyocardial ischemia, and the other qualifications nentioned, the results of this study suggest that the resence of angina is an important independent factor n prognosis. Why this is so is uncertain. It may be that he extent of ischemic heart disease is greater in patients vith angina, but there is no evidence at present to upport this hypothesis. Also unproved is the hypothesis hat angina may trigger enhanced central nervous sys- em activity resulting in an increased incidence of udden death. The absence of angina does not neces- arily indicate a benign prognosis, however, because early mortality in the asymptomatic patients with hree vessel disease was nearly 5 percent. Whether rophylactic therapy (for example, with propranolol) vould improve prognosis in this subgroup is unclear, as the role of surgery in asymptomatic patients.

APPENDIX

The Mantel-Haenszel Test for Matched Survival Data

In the past, the Mantel-Haenszel test has been applied both o matched and to stratified binary responses, and to un- natched, stratified or unstratified, survival time responses. The current study contains a trivial extension: The test has een applied to matched survival data with multiple controls. 'or completeness, this appendix reviews the theory for natched survival data with multiple controls which parallels he theory for stratified survival time responses.

Let p_{ijt} be the probability that a patient in group i (i = 1 for no pain, i = 2 for pain), and matched set j (j = 1,2, . . ., 44) dies during year t (t = 1,2,3,4,5,6,7) given that the patient is at risk (that is, observed) throughout year t. Under the logit model

$$p_{ijt} = \frac{\exp\{\alpha_i + \beta_{jt}\}}{1 + \exp\{\alpha_i + \beta_{jt}\}}$$

$$i = 1,2$$
$$j = 1,2,. . .,44$$
$$t = 1,2,. . .,7$$

β_{jt} is the joint year and matched set effect, and $\alpha_1 - \alpha_2$ is the log relative odds of death (no pain/pain), assumed constant over years and matched sets. The Mantel-Haenszel test eliminates the β_{jt} by conditioning on the number of deaths in matched set j and year t.

Let n_{ijt} = number of patients in group i, matched set j, at risk throughout year t.

Let r_{ijt} = number of deaths in group i, matched set j, among patients at risk throughout year t.

The null hypothesis $H_0 : \alpha_1 - \alpha_2 = 0$, together with the previous logit model, implies that the pain and no pain groups have identical annual survival probabilities within matched sets. Under H_0, the conditional expectation, e, and the conditional variance, v, of the number of deaths in the no pain group are

$$e = \sum_{\substack{j,t \\ n_{+jt} \geq 1}} \frac{n_{1jt} r_{+jt}}{n_{+jt}}$$

$$v = \sum_{\substack{j,t \\ n_{+jt} \geq 2}} \frac{r_{+jt} n_{1jt} n_{2jt} (n_{+jt} - r_{+jt})}{n^2_{+jt} (n_{+jt} - 1)},$$

where a "+" subscript denotes summation over the subscript.

Under H_0, the test statistic

$$\frac{(|r_{1++} - e| - .5)^2}{v}$$

is asymptotically distributed as chi-square on 1 degree of freedom.

Analysis of Exercise-Induced Changes in R Wave Amplitude in Asymptomatic Men With Electrocardiographic ST-T Changes at Rest

JOHN YIANNIKAS, MB, BS*

PETER TAGGART, MD, MRCP
BRIAN H. KELLY, MD, FRCP
RICHARD EMANUEL, DM, FRCP, FACC

London, England

Fifty asymptomatic men, 44 (88 percent) of whom were pilots or allied aviation personnel, were referred because of resting ST-T electrocardiographic changes indistinguishable from those of myocardial ischemia. Because of the nature of their occupations, cardiac catheterization was performed to establish the presence or absence of coronary artery disease. Exercise tests were performed and analyzed retrospectively with respect to exercise-induced changes in the S-T segment and R wave amplitude. The results were correlated with coronary angiographic and echocardiographic findings.

The 50 subjects were classified into two groups: Group I, 5 men with angiographically proved coronary artery disease, and Group II, 45 men without significant coronary arterial obstruction. Analysis of the S-T segment changes at peak exercise showed 21 subjects (42 percent) with a positive exercise test and 29 (58 percent) with a negative test. All subjects in Group I had a positive test. Sixteen subjects (35 percent) in Group II had a false positive result. Analysis of exercise-induced changes in R wave amplitude revealed that six subjects had a positive R wave response on the basis of sum of the changes in voltage in the leads measured ($\Delta\Sigma R$). Four of the six subjects had coronary artery disease and the other two were thought to have a cardiomyopathy. One subject with coronary artery disease had a negative R wave response. Echocardiography revealed five subjects with asymmetric septal hypertrophy; two of these had a positive exercise test and three a negative test on the basis of S-T segment criteria.

Thus, symptom-limited treadmill exercise testing of asymptomatic men with resting ST-T electrocardiographic changes produced a high incidence rate of false positive results when S-T segment criteria were used, whereas analysis of changes in R wave amplitude yielded only two false positive results, both in men who had evidence of other heart disease.

Asymptomatic and apparently healthy persons who show resting S-T segment and T wave changes indistinguishable from those of myocardial ischemia in a routine electrocardiogram present a common and difficult medical problem. Such persons have a low incidence rate of coronary artery disease,[1] and because treadmill exercise testing produces many false positive results, it may complicate rather than resolve the problem in many instances.

The few studies that have specifically examined patients with ST-T changes in the electrocardiogram obtained at rest in populations with a large incidence of coronary artery disease have shown that such changes at rest do not alter the sensitivity or specificity of the S-T segment response to exercise.[2–4] Unfortunately, the predictive value of exercise-induced S-T segment changes in asymptomatic patients with ST-T changes at rest is low.[1] Several studies[5] have suggested that beta receptor blockade can normalize the ST-T changes at rest seen in patients without

heart disease.[5] Recently,[6] when similar patients with ST-T changes at rest underwent exercise testing and subsequent coronary angiography, all false positive exercise tests were eliminated when the tests were repeated after beta receptor blockade.

There is now evidence that, in populations with a large incidence of heart disease, R wave amplitude changes during exercise have sensitivity and specificity that are comparable with the S-T segment response, and that use of this criterion can reduce the number of false positive and false negative responses.[7–9] Furthermore, R wave analysis may be of use in the diagnosis of coronary artery disease in patients with left bundle branch block[10] and in patients who are taking digitalis.[9] In both these situations the value of S-T segment analysis is limited.

The aim of this project was to assess the value of exercise-induced R wave amplitude changes in asymptomatic men with resting ST-T electrocardiographic changes, to compare these changes with the S-T segment response, and to see whether the frequency of false positive S-T segment changes could be significantly reduced.

Methods

Study group: The exercise tests of 50 consecutive asymptomatic men (44 of whom were pilots or allied aviation personnel) referred between 1975 and 1979 were analyzed in retrospect. All had ST-T changes in the resting electrocardiogram performed routinely as part of the screening process for their profession. All were then referred for cardiac catheterization because the presence of heart disease, particularly coronary artery disease, had to be excluded before they could continue with their occupations. Analysis of the S-T segment response and R wave amplitude changes during exercise was made without prior knowledge of the cardiac catheterization results.

The subjects had normal physical findings and only three were taking medication, a thiazide diuretic agent in two and hydralazine for mild hypertension in one. Subjects with evidence of left ventricular hypertrophy or conduction abnormalities in the resting electrocardiogram were excluded from study.

Exercise tests: A maximal treadmill exercise test was performed according to the multistage Bruce protocol[11] with the end points being the subjects' limit of tolerance rather than a target heart rate. The three channel Avionics monitor model 3000 and computer programme P.100 was used with the CM lead system. The three precordial leads were positioned in order to include areas of maximal S-T changes seen in the resting electrocardiogram and incorporating lead CM_5 in each case.

From the analysis of the S-T segment an exercise test was considered positive if S-T depression of at least 1 mm in comparison with the tracing at rest was present in at least six consecutive beats, measured 60 ms after the J point with reference to the P-R interval irrespective of whether the S-T segment was upsloping, downsloping or horizontal. If there was resting S-T segment depression, then a further 1 mm depression with exercise was required before the test was considered positive.

R wave measurements were made from the P-Q junction to the tip of the R wave, with the patient standing at rest, as well as peak exercise. The mean value of 10 consecutive R wave measurements was taken so as to overcome the problem of respiratory variation in R wave amplitude. A test was considered positive by R wave criteria if there was either no change or an increase in R wave amplitude at peak exercise. R wave amplitude was measured in leads CM_4, CM_5 and CM_6 and the sum of the amplitudes (ΣR) was recorded, with the change in R wave amplitude designated as ΔR for the individual leads and $\Delta\Sigma R$ for the sum of the amplitude changes in all the leads.

Echocardiography: Echocardiograms were performed in all subjects, specifically seeking evidence of occult valve disease, cardiomyopathy, asymmetric septal hypertrophy, mitral valve prolapse and pericardial disease, all conditions known to produce ST-T changes at rest and during exercise. The echocardiograms were performed using a commercially available echograph (Smith-Kline Ekoline 20A) and a 2.25 megahertz transducer focused at 7.5 cm and recording on a Cambridge strip chart recorder.

Cardiac catheterization: Left heart catheterization and coronary angiography were performed in all subjects with use of the Sones or Judkins technique. Ventriculography was performed only in the 30° right anterior oblique position at 40 frames/s. Significant coronary artery disease was diagnosed when there was a diameter narrowing of 50 percent or more in the lumen of a major vessel. Left ventricular wall motion was assessed qualitatively and contraction abnormalities were noted.

Results

Electrocardiogram at rest: Changes in the S-T segment and T wave indistinguishable from those of myocardial ischemia were present at rest in all subjects studied (Fig. 1).

Cardiac catheterization: The 50 subjects were separated into two groups according to the results of coronary angiography. Group I consisted of five patients with significant coronary artery disease: one patient with single, two with double and two with triple vessel

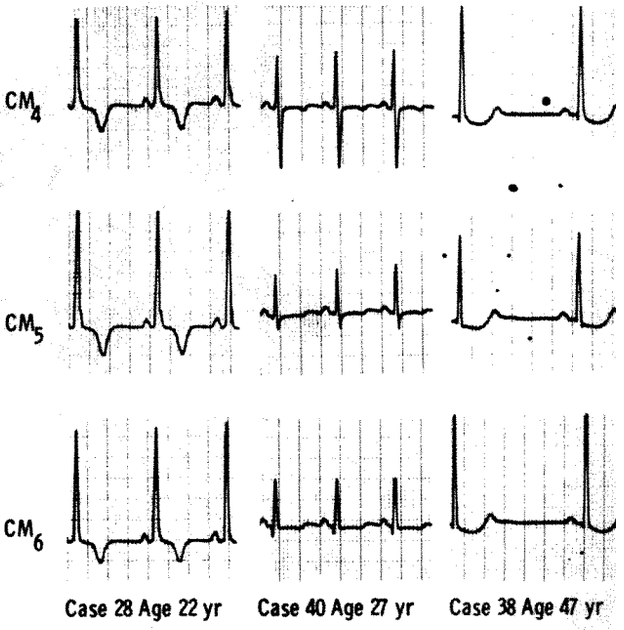

FIGURE 1. Representative changes of the S-T segment and T wave a rest.

TABLE I

Age and Heart Rates Achieved (mean ± standard deviation)

Exercise Test Result*	Age (yr)	Resting HR (beats/min)	Max HR (beats/min)
Positive (n = 21)	39.2 ± 9.6	83.7 ± 19.6	165.8 ± 18.4
Negative (n = 29)	32.7 ± 8.6	86.0 ± 15.8	173.5 ± 13.9

* S-T segment criteria.
HR = heart rate; Max = maximal.

disease. Group II consisted of 45 subjects without coronary arterial obstruction. Two of these subjects were thought to have a cardiomyopathy, with thick ventricular walls at ventriculography and increased left ventricular end diastolic pressures at rest.

Exercise testing: *S-T segment analysis:* There were 21 subjects (42 percent) who had a positive exercise test result and 29 (58 percent) a negative result. All subjects with coronary artery disease (Group I) had a positive test. Sixteen subjects from Group II had a false positive test.

Table I compares the subjects with positive and negative tests with respect to age and the resting and maximal heart rates achieved. The subjects with a positive exercise test were older, having a mean (± standard deviation) age of 39.2 ± 9.6 years compared with 32.7 ± 8.6 years in the group with a negative exercise test. The maximal heart rates achieved were 165.8 ± 18.4 beats/min for those with a positive test and 173.5 ± 13.9 beats/min for those with a negative test. The number of patients with coronary artery disease was too small to give meaningful sensitivity and specificity values.

R wave analysis: The distribution of change in R wave voltage from rest to peak exercise (ΔR) in the three leads and the sum of the change in these three leads (ΔΣR) are shown in Figure 2. On the basis of ΔΣR there were six subjects whose test was considered positive. Of these six subjects, four had coronary artery disease—one with single, one with double and two with triple vessel disease. The other two subjects with positive findings on R wave analysis were thought to have a cardiomyopathy. In 44 subjects the R wave amplitude decreased. One of these subjects had coronary artery disease (90 percent distal obstruction of a small circumflex artery, 50 percent stenosis of the right coronary artery and associated mild generalized reduction in left ventricular function). The other 43 subjects with reduced R wave amplitude had normal cardiac catheterization findings.

Analysis of lead CM_6 revealed positive results in six subjects; four of these had coronary artery disease, one probably had a hypertrophic cardiomyopathy, and one had normal cardiac findings. Analysis of lead CM_5 yielded five positive results, four in subjects with coronary artery disease and one in a subject with probable hypertrophic cardiomyopathy. Although the number of subjects with heart disease was small, it was believed that ΔΣR analysis gave the best results because the amplitude changes were greater (Fig. 2) and because all subjects with a positive test had cardiac disease.

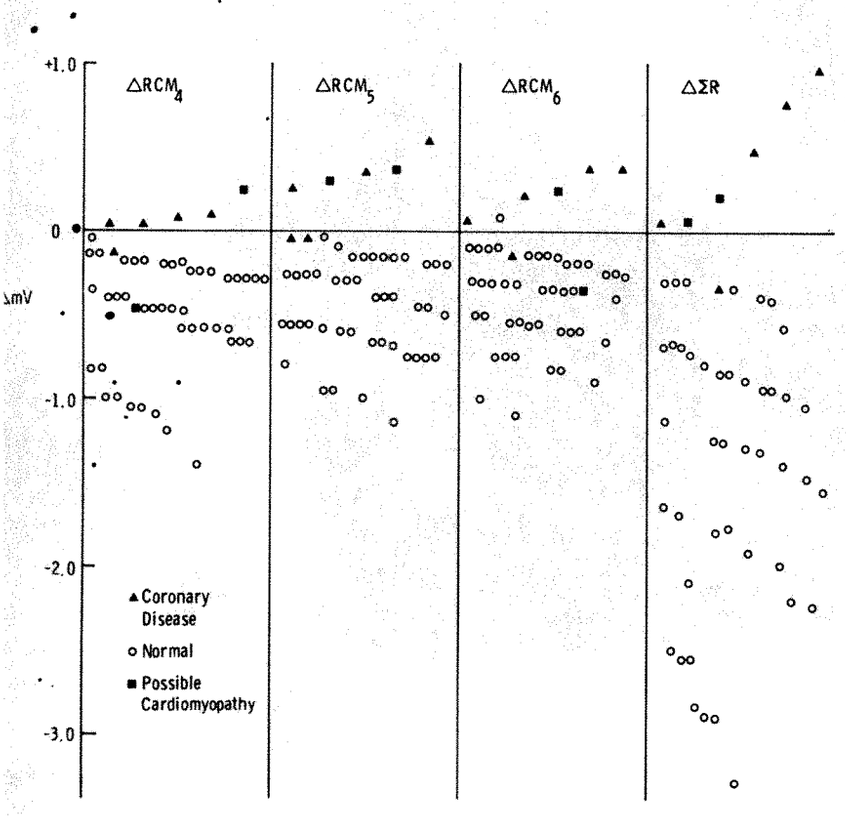

FIGURE 2. The distribution of change in voltage from rest to peak exercise in the three leads recorded and the sum of these changes. ΔmV = change in voltage (1 mV = 10 mm); ΔRCM_4, ΔRCM_5, ΔRCM_6 = change in voltage in the CM leads recorded; ΔΣR = sum of the changes in voltage in the leads recorded.

TABLE II

Age, Heart Rates Achieved and Degree of R Wave Amplitude Change (mean ± standard deviation)

R wave change	Age (yr)	Resting HR (beats/min)	Max HR (beats/min)	$\Delta\Sigma R$ (mm)	$\%\Delta\Sigma R$
Reduced R waves (n = 44)	35.1 ± 9.5	84.8 ± 17.8	171.4 ± 16.0	−14.0 ± 8.1	−24.4 ± 14.7
Increased R waves (n = 6	38.3 ± 9.8	87.6 ± 17.3	163.8 ± 19.2	+4.2 ± 3.9	+14.9 ± 19.4

$\Delta\Sigma R$ = sum of the change in R wave amplitude in the three leads measured; HR = heart rate; Max = maximal; $\%\Delta\Sigma R$ = percent change in amplitude in ΣR.

Table II compares those subjects who had an increase in R wave amplitude with those who had a decrease, when analyzing $\Delta\Sigma R$ with respect to age, heart rates achieved and degree of amplitude change. The maximal heart rate achieved was comparable in both groups (mean 163.8 ± 19.2 beats/min) in those with increased R wave amplitude and 171.4 ± 16.0 beats/min in those with decreased R wave amplitude. In the group with increased R wave amplitude only one subject had a heart rate of less than 150 beats/min. The reduction in voltage (mean −14.0 ± 8.1 mm) was greater than the increase in voltage (+4.2 ± 3.9 mm). The decrease in R wave amplitude was significant ($p < 0.01$). The decrease in R wave amplitude in the individual leads was also significant ($p < 0.01$). In those with R wave amplitude changes satisfying positive criteria, the changes were not significant in lead CM_4 ($p = 0.5$), but were significant in leads CM_5 and CM_6 and in the sum of the three leads ($\Delta\Sigma R$) ($p < 0.01$, < 0.02 and < 0.05, respectively). These statistics are acceptable considering that the definition of a positive test included those subjects with no change in R wave amplitude.

Table III shows left ventricular function data in the six subjects with positive R wave amplitude changes when analyzing $\Delta\Sigma R$. Four of the subjects had increased left ventricular end-diastolic pressure and two had segmental left ventricular wall hypokinesia.

Echocardiograms: A septal to free posterior left ventricular wall ratio of greater than 1.5 was present in five subjects. Although this isolated finding when seen in the elderly may be a normal variant,[12] all five subjects were less than 41 years old and this finding was considered abnormal. It has been reported[15] that subclinical symmetric and asymmetric septal hypertrophy (ASH) may be a cause of false positive S-T segment responses to exercise but, of the five subjects with asymmetric septal hypertrophy, two had a positive exercise test and three had a negative exercise test (on the basis of S-T segment criteria).

Discussion

Significance of S-T changes at rest in asymptomatic persons: The need to identify persons with latent coronary artery disease is nowhere better illustrated than in those whose occupations involve public safety (drivers of public service vehicles, firemen, pilots and air traffic controllers, for example). Routine electrocardiograms are now performed in such persons as well as in various screening services and as part of certain insurance assessments. Joy[14] found, when analyzing 5,217 electrocardiograms performed in civil and professional aircrew and air traffic control officers, that ST-T changes were the most frequent electrocardiographic abnormality, occurring in 3.9 percent of the electrocardiograms. The majority of these abnormalities were found in apparently healthy and asymptomatic people, illustrating that these changes in a routine electrocardiogram in an asymptomatic population present a not infrequent clinical problem.

Resting changes of the S-T segment and T wave, in the absence of heart disease, are well known and have been variously explained.[15–17] However likely these explanations are, the changes are indistinguishable from those of myocardial ischemia and the subjects often undergo treadmill exercise testing. Rifkin and Hood,[18] by applying Bayes' theorem of analysis to exercise testing, showed that the predictive value of the S-T segment response to exercise is inversely proportional to the prevalence of coronary artery disease in the population being studied. Hence, in asymptomatic patients who have a low incidence rate of disease, the predictive value of a positive test is significantly reduced and the number of false positive responses is high.[1]

TABLE III

Ventricular Function Data in the Six Subjects With Increased R Wave Amplitude

	Subjects					
	1	2	3	4	5	6
$\Delta\Sigma R$ (mm)	+7.7	+0.5	+9.9	+0.4	+4.6	+2.0
LVEDP (mm Hg)	20	20	21	10	—	13
Hypokinesia	Apical	N	Inferior	N	N	N

$\Delta\Sigma R$ = sum of the change in amplitude in the three leads measured in millimeters (1 mV = 10 mm); LVEDP = left ventricular end diastolic pressure; N = normal segmental wall motion.

False positive S-T response to exercise: In our study there was a high incidence rate of false positive S-T segment responses, although most of the causes of false positive tests had been excluded. Twenty-one subjects (42 percent) had a positive exercise test, and 16 of these were false positive tests. When the criteria for a positive test were made more stringent than those routinely used in this unit (with a further 1.5 mm depression if there was S-T segment depression in the resting electrocardiogram, and 1.5 mm depression if the S-T segment response was upsloping and measured at 80 ms after the J point) all the positive tests remained positive.

If a positive S-T segment response had been the indicator for performing cardiac catheterization, 16 subjects (76 percent) in our group with a positive exercise test would have been studied unnecessarily. Resting ST-T changes in patients with a large prevalence of coronary artery disease do not influence the predictive value of the S-T segment response to exercise.[2–4] However, when these ST-T changes were present in the asymptomatic population studied, the high incidence rate of false positive results seen was similar to that found when any asymptomatic population is screened.[1,18]

R wave responses to exercise: Analysis of amplitude changes of the R wave with exercise in populations with a large prevalence of disease has yielded comparable results with those of S-T segment analysis in several studies.[7–9] As mentioned, R wave analysis in subgroups of patients in whom the S-T segment response to exercise is of limited value has yielded encouraging results.[9,10] In the selected population we studied, coronary artery disease was correctly diagnosed in four of the five patients with this disease when R wave criteria were applied. The false positive R wave amplitude changes reported in other studies have often occurred in patients with myocardial disease with increased left ventricular end-diastolic pressure.[9,19] In keeping with these results, the two false positive R wave results in our study occurred in subjects with evidence of myocardial disease confirmed on echocardiography and ventriculography. Both subjects had increased left ventricular end diastolic pressure at rest.

The theoretical reasons for a change in R wave amplitude are many[20–22] and the few studies that have addressed themselves to establishing the reasons for the change in amplitude of the R wave during exercise have yielded varied results.[23–26] It has recently been suggested[23] that the increase in R wave amplitude after exercise in patients with coronary artery disease may be due to the inability of these patients to achieve an adequate heart rate at peak exercise. As Wolthius et al.[27] showed in normal subjects, there is a slight increase in R wave amplitude up to a heart rate of about 140 beats/min and then a fairly dramatic reduction in amplitude at higher rates; hence, if these rates are not achieved, an increase in R wave amplitude would be recorded. In our study (Table II), the heart rates achieved in those with increased R wave amplitude and in those with decreased R wave amplitude were comparable and significantly above 140 beats/min. An inadequate rate, therefore, is clearly not the reason for the increase in R wave amplitude in the group studied. In fact, the hemodynamic responses to exercise were normal in all our subjects. Whatever the reasons are for the change in R wave amplitude during exercise, our study demonstrates that the number of false positive exercise responses is significantly reduced when R wave amplitude changes rather than S-T segments are analyzed. Furthermore, all subjects who had a false positive R wave response were thought to have other heart disease. As previously shown,[6] beta adrenergic blockade may abolish the false positive S-T segment response to exercise in asymptomatic patients with ST-T wave change at rest. Our study demonstrates that, in similar subjects, analysis of exercise-induced R wave amplitude changes gives comparable results.

Clinical implications: The reliability of changes in R wave amplitude must be further studied before use of this criterion obviates the necessity for coronary angiography when ST-T changes at rest and a positive exercise test occur in patients whose occupation involves public safety. However, among asymptomatic men in other occupations with ST-T changes at rest, diminished R wave amplitude after exercise, even in the presence of a positive test based on S-T segment criteria, strongly suggests the absence of coronary artery disease, making coronary angiography unnecessary. There are many unanswered questions about this group of asymptomatic subjects with ST-T changes at rest. The key issues as to the nature of these abnormalities in the absence of cardiac disease and the natural history of these changes remain unresolved.

The ventricular effective refractory period is commonly employed as a measurement of ventricular excitability. Because the current strength used to make this determination varies among laboratories, the relation of refractoriness and current was examined over a range of current strengths from 0.1 to 10 mA. Sixty determinations of refractoriness at variable current strengths were made in 40 patients using the extrastimulus technique with a rectangular pulse of 1 ms duration. These data were obtained by measuring the effective refractory period at threshold current and at 0.25 to 0.50 mA increments from threshold up to 10 mA. In these studies the drive stimulus (S_1) and extrastimulus (S_2) were kept at the same amplitude. In all patients the ventricular effective refractory period decreased as the current increased. The total decrease ranged from 8 to 100 ms (mean ± standard deviation 36.9 ± 17.1). The current strength at which the ventricular effective refractory period became fixed (that is, less than 2 ms change in ventricular effective refractory period with further increase in current strength) varied among the patients, but in all instances equaled or exceeded 1.8 mA, which in all but three patients was greater than three times threshold. The curves relating current strength and refractoriness were shifted to the left at shorter cycle lengths with no change in threshold.

These data suggest that (1) current strength-effective refractory period curves more completely characterize ventricular excitability than does a ventricular effective refractory period at single current strength; and (2) studies of drug effects, alterations of autonomic tone, or reentrant arrhythmias, which may affect or are affected by ventricular refractoriness, may be enhanced by more complete measurements of refractoriness afforded by the current strength-effective refractoriness curves.

Determination of the ventricular effective refractory period is routinely employed as a measurement of excitability in clinical electrophysiology. The effective refractory period has been defined as the period following depolarization during which no response can be elicited by premature stimuli at some multiple of threshold. Refractory period measurements are made using the extrastimulus method, but current strengths ranging from threshold to twice diastolic threshold have been used in different laboratories.[1,2] Adrian[3] demonstrated that in excitable tissue the period of nonexcitability shortens as the strength of the applied extrastimulus is increased. This phenomenon has been observed repeatedly in intact mammalian hearts and in isolated cardiac tissues.[4–7] Therefore, the refractory period is a measurement that is meaningful only when related to the strength of the stimulus.[8]

Measurements of the current dependence of refractoriness have been used to characterize more completely the excitability of isolated cardiac tissue by expressing the refractory period as a function of the applied

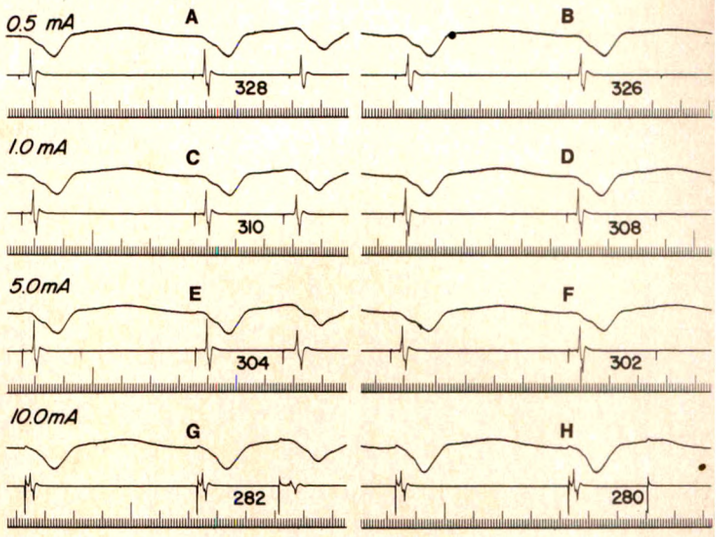

FIGURE 1. Method of measuring current-dependent changes in refractoriness. Analog records of surface lead V_1 and intracardiac electrograms from the right ventricular apex are displayed from top to bottom in each panel. In panel **A**, a premature stimulus, current strength 0.5 mA, was introduced during a basic ventricular drive of a cycle length of 600 ms, at a coupling interval of 328 ms and produced a propagated response. **B**, at the same current strength, a premature stimulus introduced at a coupling interval 2 ms shorter failed to capture the ventricle. **C**, increasing the current-strength of both the ventricular drive and the extrastimulus resulted in capture of the ventricle down to a coupling interval of 310 ms. But shortening of the coupling interval to 308 ms at the new current strength eventually leads to refractoriness (**D**). The cycle is repeated with 0.25 mA increments in current strength from threshold to 5 mA, and in 0.5 mA increments from 5 to 10 mA (**E** to **H**).

current.[9] However, similar analyses have not been done systematically in the human ventricle. Because assessment of ventricular excitability has implications for understanding the mechanisms of arrhythmias and the properties of antiarrhythmic agents, we undertook this study to characterize the relation of current strength to refractoriness in order to analyze the excitability of the human ventricle and to determine a better measure of refractoriness.

Methods

Electrophysiologic technique: The relation between ventricular effective refractory period and stimulus strength (current strength-effective refractory period curve) was studied in 40 patients, 12 women and 28 men, ranging in age from 16 to 82 years, undergoing electrophysiologic evaluation for clinical indications. In each patient tripolar and quadripolar electrode catheters (1 cm interelectrode distance) were introduced percutaneously by way of the right or left femoral or antecubital veins and positioned under fluoroscopic guidance in the high right atrium, atrioventricular (A-V) junction (His bundle recording site), coronary sinus and right ventricular apex. Stimulation was achieved with the quadripolar catheter firmly lodged at the right ventricular apex, using the distal electrode pair, while electrograms were recorded from the proximal pair. Stability was confirmed by low reproducible late diastolic thresholds and by visual observation of catheter position under fluoroscopy.

Ventricular effective refractory period determinations were made with the extrastimulus technique using bipolar stimulation, with the distal pole as cathode. Current was delivered as a rectangular impulse of 1 ms duration and variable current strength (0.2 to 10.0 mA). The intracardiac recordings were simultaneously displayed with multiple electrocardiographic leads, usually leads I, II and V_1, on an eight channel oscilloscope (Electronics for Medicine).

Data were obtained as follows: Diastolic threshold was determined by stimulating the ventricle during late diastole (more than 75 percent of the R-R interval). With use of a programmable stimulator (Bloom Associates Ltd., Inc., Narberth, Pennsylvania), progressively more premature ventricular extrastimuli (S_2) were introduced at the right ventricular apex after the eighth paced complex (S_1) of a basic drive at a cycle length of 600 ms. The S_1-S_2 interval was reduced by one to 2 ms decrements until S_2 failed to initiate a ventricular response. This interval, the effective refractory period, was determined first at diastolic threshold. Then the intensity of S_1 and S_2 was increased simultaneously in 0.25 mA increments up to 5 mA, then in 0.5 mA increments up to 10 mA. The S_1-S_2 interval was kept constant at the previously refractory interval until a current intensity was found at which S_2 again initiated a ventricular response. At this new current, the S_1-S_2 interval was decreased in 1 to 2 ms decrements until S_2 was again refractory. The current was then increased and the interval held constant until a response was initiated. This cycle was repeated up to 10 mA. Selected analog records from such a current strength-effective refractoriness curve determination are shown in Figure 1. In patients without ventriculoatrial conduction, the atrium was paced simultaneously with the ventricle to avoid intermittent ventricular capture by atrial depolarizations.

The reproducibility of the effective refractory period at any current and interval was verified by multiple (two of three) determinations before changing the current. Diastolic threshold was measured several times during the study to insure stability. The entire process was repeated at one or more additional cycle lengths in 15 patients. All data are reported as mean ± standard deviation unless otherwise specified.

Results

Effects of Changes in Current Strength

Sixty determinations of current strength-effective refractory period curves were made in 40 patients. Right ventricular threshold ranged from 0.2 to 2.5 mA (mean 0.81 ± 31). In all patients the effective refractory period of the ventricle decreased with increasing current (Fig. 2). The ventricular effective refractory period at threshold ranged from 204 to 350 ms (mean 268.3 ± 35.4), whereas that at 10 mA ranged from 180 to 294 ms

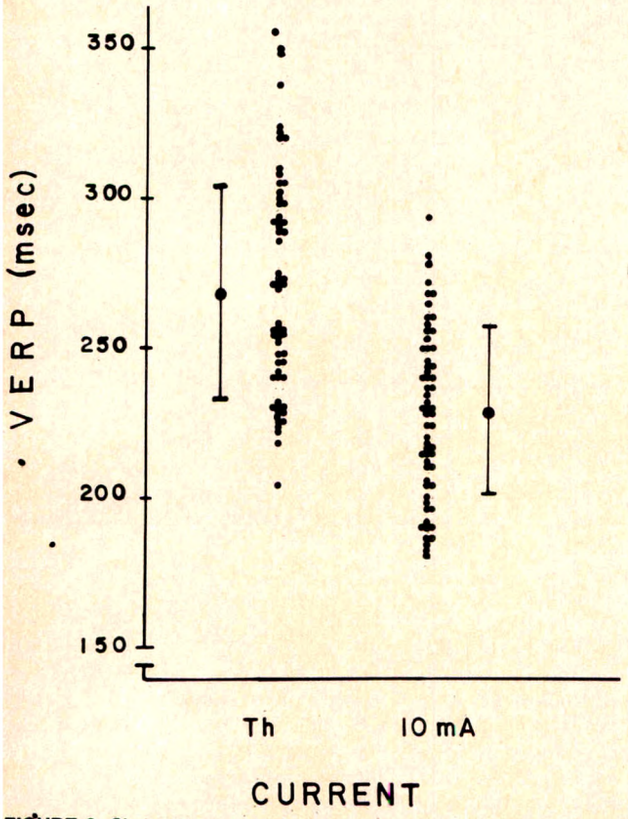

FIGURE 2. Change in ventricular effective refractory period with increasing current strength. Ventricular effective refractory periods (VERP) measured during 60 current strength-effective refractory period determinations are plotted on the ordinate versus two selected current strengths (that is, threshold [Th] and 10 mA on the **abscissa**). The mean value for all 60 curves at threshold current is significantly greater than that at 10 mA.

(mean 229.4 ± 28.2). This difference was significant ($p < 0.001$). The relation between current strength and the ventricular functional refractory period was not systematically studied in each case. In patients in whom it was examined, the functional refractory period also decreased with increasing current strength, although not to the same degree as the ventricular effective refractory period.

The relation between ventricular refractoriness and current strength was nonlinear. At low current strength (<4 mA) small increments in current (1 mA) resulted in large changes in effective refractory period (10 to 50 ms), whereas at higher current strengths (>6 mA) the change in effective refractory period of the ventricle with a 1 mA increment in current was small, and the curve became steep. A typical curve relating effective refractory period to current strength is shown in Figure 3.

The total change in the effective refractory period of the ventricle with increasing current, from threshold to 10 mA, ranged between 8 and 100 ms (mean 36.8 ± 16.1). The total change in ventricular effective refractory period with increasing current from twice threshold to 10 mA was 27.1 ± 10.9. In three patients with a high diastolic threshold (not attributable to unstable catheter position) (2.0 to 2.5 mA), the total change in refractory period was only 8 to 10 ms. However, in the majority of patients (72 percent) the total change in refractory period was 20 to 40 ms (Fig. 4).

The current strength at which the curve became steep, defined as the current beyond which no more than a 2 ms change in ventricular refractory period occurred, averaged 6.73 ± 1.9 mA. In Figure 5 threshold current is compared with the current at which the curve

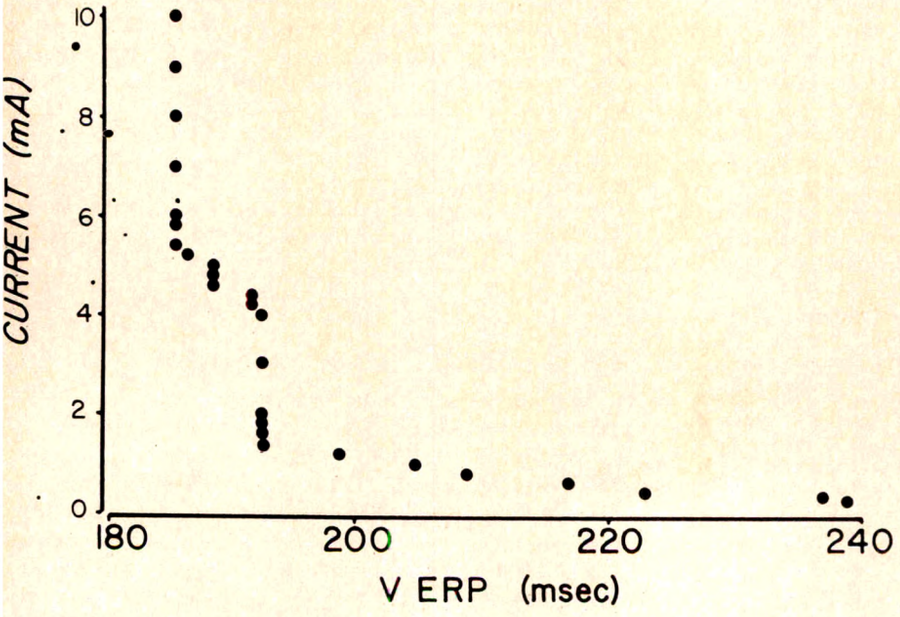

FIGURE 3. Typical curve relating current strength and ventricular refractoriness. The ventricular effective refractory period (VERP) at a given current strength (**abscissa**) is plotted against the current strength of the stimuli (**ordinate**). At diastolic threshold, 0.35 mA, the ventricular effective refraction period is 238 ms. With increases in stimulus current there is a gradual decrease in the effective refractory period until it becomes fixed at 185 ms, despite further increases in current from 5 to 10 mA.

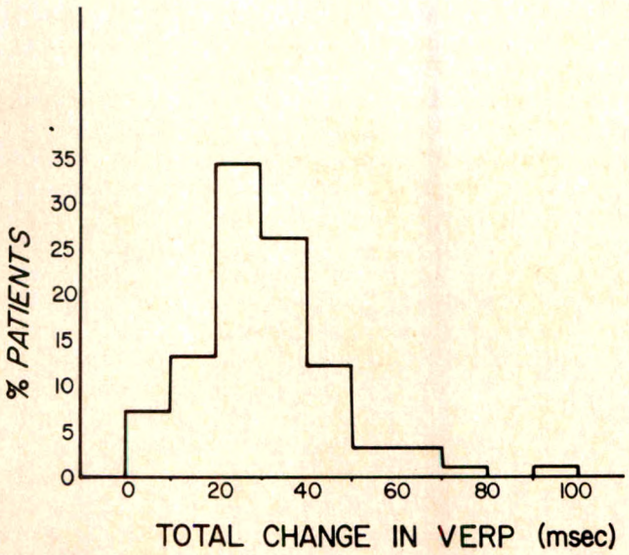

FIGURE 4. Analysis of the total change in ventricular effective refractory period (VERP) with increasing current. The total change in ventricular effective refractory period with increasing current from threshold to 10 mA (**abscissa**) is plotted against the percent of patients demonstrating such a total change. In three patients (7 percent) with a high diastolic threshold, the total change in ventricular effective refractory period was less than 10 ms; in 72 percent of the patients the total change with increasing current was between 20 and 40 ms.

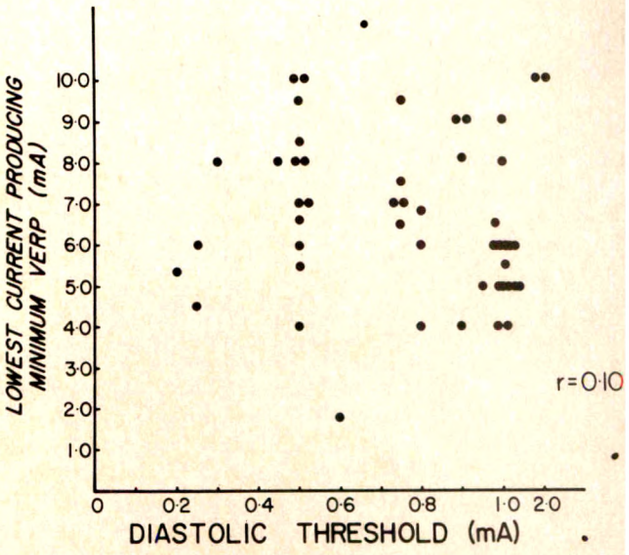

FIGURE 5. Relation of the current strength at which the ventricular effective refractory period became fixed to diastolic threshold. Diastolic threshold in ms (**abscissa**) is plotted against the current strength in mA at which the ventricular effective refractory period became fixed (**ordinate**). By linear regression analysis there is no correlation between these two variables (r = 1.0). In all but one determination, the current strength associated with the fixed minimal ventricular effective refractory period was greater than 4.0 mA.

became steep. This plot demonstrates that there was marked scatter in the values of the current required to reach the steep portion of the current strength-effective refractory period curve. Moreover, with any diastolic threshold the current at the onset of the steep portion of the curve was quite variable. There was no relation between threshold current and the current at which the curve became steep. In all but one patient the onset of the steep portion of the curve occurred at 4 mA or greater, and was greater than three times threshold in all but the two patients whose effective refractory period changed less than 10 ms. In these two patients (three curves) with a threshold of 2.5 mA, the steep part of the curves occurred at 6.5 or 7.0 mA. In 30 patients the change in the effective refractory period of the ventricle was less than or equal to 2 ms as current was increased from 7 to 10 mA, whereas the change in effective refractory period exceeded 25 ms as current was increased from threshold to 7 mA. The effect of stimulus strengths greater than 10 mA was not determined.

Effect of Changes in Cycle Length

The effect of cycle length on this relation between current strength and refractoriness was studied in 15 patients. Current strength-effective refractory period curves were measured at two drive cycle lengths (600 and 400 ms) in 15 patients and at a third drive cycle length (800 ms) in 5 of the 15. Shortening the basic drive cycle length from 800 to 600 or from 600 to 400 ms did not alter the shape of the current strength-refractory period curve. An example for a change in cycle length from 600 to 400 ms is shown in Figure 6. Although late diastolic threshold was unchanged at the shorter cycle lengths, refractory periods were shorter at each current strength; that is, the curves were shifted to the left. Thus, at a cycle length of 800 ms the effective refractory period at threshold ranged from 305 to 350 ms (mean 327.5 ± 31.8) and at 10 mA ranged from 260 to 281 ms (mean 270.5 ± 14.9). At a cycle length of 600 ms the effective refractory period at threshold and 10 mA ranged, respectively, from 245 to 305 ms (mean 269.7 ± 29.2) and from 212 to 265 ms (mean 237.8 ± 18.2), whereas at a cycle length of 400 ms the ventricular effective refractory period at threshold and 10 mA ranged, respectively, from 218 to 258 ms (mean 233 ± 15.1) and from 190 to 231 ms (mean 202.1 ± 14.9). The differences in the mean effective refractory period at a given current strength for each cycle length were statistically significant ($p < 0.001$). However, the total change in effective refractory period with increasing current strength was essentially unaltered when determined at the three cycle lengths, averaging 42.8 ± 19.5 ms at a cycle length of 800 ms, 38.1 ± 8 ms at a cycle length of 600 ms and 31.4 ± 7 ms at a cycle length of 400 ms ($p > 0.05$).

Discussion

The excitability of cardiac muscle, as determined by applied extrinsic stimuli, has been evaluated in intact mammalian hearts and isolated heart muscle using the strength-interval relation.[4,6,10] As stimulation occurs earlier in the cardiac cycle, more current is required to

initiate a response. The curve relating current strength and refractoriness becomes steep at a specific coupling interval that is related to the absolute refractory period (that is, the period during which no stimulus strength will excite the tissue). These curves are reproducible in different species and have the characteristic that at low current strengths small changes in current cause large changes in refractory period, whereas at high current strengths changes in refractory period with similar changes in current approach 0. The relation between stimulus strength and refractory period is therefore nonlinear.

This study has evaluated the effects of current intensity on ventricular refractoriness in the human ventricle. We have shown that the characteristic nonlinearity of the relation between current strength and refractoriness holds in the human ventricle using bipolar stimuli of 1 ms duration, delivered through a transvenous intracardiac electrode catheter with an interelectrode distance of 1 cm. The shape of the current strength-effective refractory period curve is in some respects similar to the strength-interval curves observed in intact mammalian hearts and isolated cardiac tissue.[4,5,10]

Moreover, cycle length-dependent effects on the current strength-effective refractory period relation have been demonstrated. Decreased cycle length has been shown to be associated with a decreased ventricular effective refractory period in the human heart at twice diastolic threshold.[1,2] Our results extend this observation over a range of current strengths. In the present study, as cycle length was shortened from 800 to 600 to 400 ms, the ventricular effective refractory period decreased at comparable current strengths. Although threshold current remained unchanged as did the general configuration of the curve, the steep portion of the curve shifted leftward. This indicates that the rate of recovery of excitability occurs earlier at shorter cycle lengths, and may in part be related to shortening of the action potential associated with decreased cycle lengths.

Importance to clinical electrophysiology: Our results have implications for clinical electrophysiology. The ventricular effective refractory period is a variable that is used to define the functional characteristics of the ventricle. We have shown that the measured ventricular effective refractory period in man varies in a predictable way with current strength, and we believe that this variable could be more completely and precisely characterized by measuring the current strength-effective refractory period curve. The determination of the effective refractory period at multiple current strengths, rather than at one current strength probably provides a more accurate measure of excitability[8] because a change in excitability at current strengths higher or lower than that used for testing would otherwise go undetected.

More precise determination of ventricular refractoriness would be important in studies of the effects of drugs[11] or alterations in autonomic tone[12] on basic electrical characteristics of the ventricle, such as excitability. In addition, since the ability to initiate or terminate reentrant arrhythmias by programmed stimulation is dependent on the refractoriness of the limbs of the reentrant circuit,[13–15] studies of such arrhythmias would be facilitated by precise measurements of tissue refractoriness of the circuit. In this regard determination of the behavior of the ventricular functional refractory period as well as the effective refractory period with current strength is pertinent, since the functional refractory period determines the shortest ventricular coupling interval that can be achieved to influence the reentrant circuit.

Utility of the modified strength-interval relation: Our data suggest that if the effective refractory period of the ventricle is determined at a single current

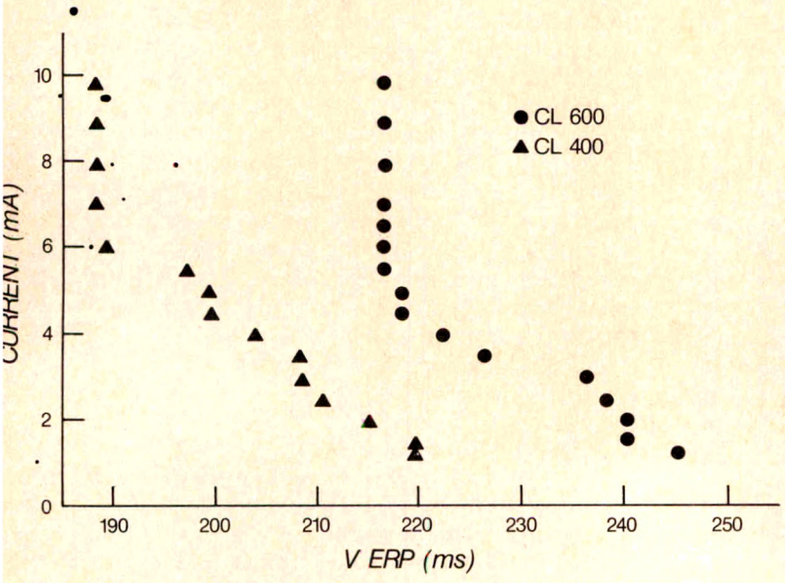

FIGURE 6. Effect of cycle length on the relation of ventricular refractoriness and current. Curves relating ventricular effective refractory period (VERP), and current strength of applied stimuli, measured during refractory period determinations at two different drive cycle lengths are plotted as in Figure 5. **Closed circles** represent measurements made at a basic cycle length (CL) of 600 ms and **closed triangles** those made at a basic cycle length of 400 ms. At the shorter cycle length late diastolic threshold is unchanged. The ventricular effective refractory period at all current strengths is decreased at the shorter cycle length, causing the curve to be shifted to the left. However, the curves become steep at similar current strengths (5.5 mA at 600 ms and 6.0 mA at 400 ms).

strength, it would be more appropriate to do so at a current strength at which changes in current produced minimal changes in the effective refractory period, that is, at the steep portion of the curve. As in the strength-interval relation, the onset of the steep portion of the curve reflects the end of the ventricular relative refractory period and the onset of the irresponsive interval or absolute refractory period. Although the current strength at which this occurs varies considerably from patient to patient, our data show that one can generally predict that the steep portion of the curve will occur at current intensities between 7 to 10 mA.

Relation to isolated tissue studies: Current dependence of refractoriness has not been extensively studied in human beings. Gettes et al.[16] measured strength-interval relations in the right ventricle of people with A-V block requiring pacemakers, and showed that it is affected by changing potassium and calcium concentration in the blood. However, most of the information on ventricular excitability has been gathered from mammalian hearts,[7,10] isolated cardiac tissue[4] or Purkinje fibers.[17]

The curves obtained in our study reveal the same phenomenon observed in animals, that is, the effective refractory period shortens with increasing current. However, there is a significant difference. In animal studies an interval was found at which the muscle becomes easier to excite; that is, less current is required than at longer coupling intervals. This has been referred to as a supernormal period and has been found to correlate with the so-called vulnerable period,[6] during which bursts of extrastimuli more easily induce ventricular fibrillation. Our technique does not permit observation of this phenomenon, because it requires determination of a new threshold at each coupling interval, rather than increasing current as extrastimuli are moved earlier in the cycle. Therefore, although the current strength-effective refractoriness curve as determined by our technique demonstrates current-dependent changes in refractoriness, it cannot evaluate the "supernormal" period in the human heart.

Limitations of the technique: Of necessity, refractoriness in the human heart is defined as the failure to induce a propagated response recorded by a bipolar electrode pair 1 cm away from the site of stimulation. Therefore in the intact human heart using the extrastimulus technique, one cannot distinguish between failure of a stimulus to excite the cardiac cell and failure to conduct locally and generate a propagated response.

An additional problem is the effect of the current strength of the drive stimulus S_1 on the ability of the premature stimulus to evoke a response. In the present study, the current intensity of S_1 always equaled that of S_2. There is evidence in isolated atrial tissue[4] that increasing the strength of S_1 will shorten the absolute refractory period of the tissue. Thus, current strength-effective refractoriness curves determined with constant current intensities of S_1 may be somewhat different from those of our study.

Furthermore, the spatial arrangement of the electrodes may have some influence on the current strength-effective refractoriness relation,[8] a factor not addressed in this study. In isolated tissue preparations, close bipolar plunge electrodes or microelectrodes are used to pass current and record. The interelectrode distances in these cases are much smaller than the 1 cm interelectrode distance found with the standard electrode catheters employed clinically. The effects of smaller interelectrode distances on the current strength-refractoriness relation in the human heart require further examination.

Clinical implications: Regardless of the cell mechanism, the current strength-effective refractory period relation does measure excitability of the ventricle as defined by how soon after a previous propagated response (S_1) and with how much current an extrastimulus (S_2) can elicit a propagated response. More importantly, the current strength-effective refractoriness relation can be used as a tool in clinical electrophysiology to assess accurately changes in ventricular excitability. Finally, the current strength-effective refractory period relation more precisely defines ventricular refractoriness, and may allow a more accurate analysis of reentrant arrhythmias and the effects of pacing or drugs on these arrhythmias.

Acknowledgment

We thank Marie Coscia and Bettie Kaplan for their assistance in preparing the manuscript. We also acknowledge the technicians in the Cardiac Electrophysiology Laboratory, and especially thank John A. Kastor, MD, Chief of the Cardiovascular Section, for his continued support and encouragement.

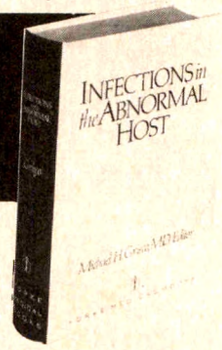
INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand, diagnose, and manage the many infections which strike patients whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • The Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Abnormalities • The Complement System in Human Disease • Structure and Function of Immunoglobulins • Human Lymphocyte Subpopulations: Surface, Intracellular, Enzymatic Markers and Functions • Congenital and Acquired Primary Disorders of B and T Lymphocyte Function • Drug-induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous, Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms and Relationship to Nosocomial Infections • The Effects of Malnutrition on Host Responses and the Metabolic Sequelae of Infections • Humoral and Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections • Mycobacterial Infections • Viral and Chlamydial Infections • Protozoal and Helminthic Infections • Infections Complicating the Transfusion of Blood, Blood Products, Animal Exposure and Animal Products • Infections Complicating the Alcoholic Host • Infections in Parenteral Narcotic and Drug Abusers • Infections Complicating Uremia and Organ Transplantation • Infections in Patients with Neoplastic Diseases • Infections Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffuse Pneumonias • Host Deficiency States and Central Nervous System Infections • Genitourinary Infections • Infections Complicating the Rheumatic Diseases • Endovascular and Prosthetic Implant Infections • Intraocular Manifestations of Systemic Infections • Selected Histopathologic Responses • The Microbiology Laboratory in Diagnosis and Therapy • Infections Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharmacology and Toxicity • Chemotherapy for Viral and Chlamydial Infections • Chemotherapy for Protozoal and Helminthic Infections • Infection Prevention in Patients with Cancer and Granulocytopenia • Immunologic Reconstitution • Gamma Globulin and Vaccine Therapy • Index

Norpace®
(disopyramide phosphate)

Before prescribing Norpace (disopyramide phosphate), please consult current complete prescribing information, a summary of which follows. ***Indications:*** *For suppression and prevention of recurrence of the following cardiac arrhythmias when they occur singly or in combination: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular contractions of multifocal origin; paired premature ventricular contractions (couplets); and episodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with D.C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It is also equally effective in treating primary cardiac arrhythmias and those which occur in association with organic heart disease including coronary artery disease. Oral Norpace has not been adequately studied in patients with acute myocardial infarction or with persistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due to digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients with serious ventricular ectopic activity has not been established.* ***Contraindications:*** *Cardiogenic shock, preexisting second- or third-degree AV block (if no pacemaker is present), or known hypersensitivity to the drug.* ***Warnings: Norpace may cause or worsen congestive heart failure (CHF) or produce severe hypotension as a consequence of its negative inotropic properties. Hypotension has been observed primarily with primary cardiomyopathy or inadequately compensated CHF. Norpace should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac arrhythmia. Patients with a history of heart failure may be treated with Norpace, but careful attention must be given to maintaining cardiac function, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace should be discontinued and, if necessary, restarted at a lower dosage only after adequate cardiac compensation has been established. Norpace should be discontinued if significant widening (greater than 25%) of the QRS complex occurs. Prolongation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Patients who have evidenced prolongation of the Q-T interval in response to quinidine may be at particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, the patient should be monitored closely, and discontinuation of Norpace considered. In rare instances significant hypoglycemia has been reported during Norpace therapy. The concomitant use of Norpace with other Type 1 antiarrhythmic agents should be reserved for patients with life-threatening arrhythmias who are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may produce serious negative inotropic effects, or may excessively prolong conduction. Patients receiving more than one antiarrhythmic drug must be carefully monitored. If first-degree heart block develops, the dosage of Norpace should be reduced. If the block persists, continuation of Norpace must depend upon an assessment of benefit versus risk. Development of second- or third-degree AV block or uni-, bi- or trifascicular block requires discontinuation of Norpace, unless the ventricular rate is adequately controlled by a pacemaker. Because of its anticholinergic activity, Norpace should not be used in patients with glaucoma, myasthenia gravis or urinary retention, unless adequate overriding measures are taken.*** ***Precautions:*** *Patients with atrial flutter or fibrillation should be digitalized prior to Norpace administration to ensure that drug-induced enhancement of AV conduction does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Norpace is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-White syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may develop significant hypotension in response to the usual dosage of Norpace. Norpace dosage should be reduced in patients with impaired renal or hepatic function and the electrocardiogram carefully monitored for signs of overdosage. Antiarrhythmic drugs may be ineffective in patients with hypokalemia. Therefore, any potassium deficit should be corrected before instituting Norpace therapy. Safe use in pregnancy has not been established. Disopyramide has been found in human fetal blood.* ***Norpace has been reported to stimulate contractions of the pregnant uterus.*** *Use of Norpace in pregnant women requires that the potential benefit be weighed against possible hazards to the fetus. Following oral administration, disopyramide has been found in human milk at a concentration not exceeding that in plasma. If use of the drug is deemed essential, an alternate method of infant feeding should be instituted. Effects of Norpace on the fetus during delivery or on the course of labor and delivery are unknown. Safety and effectiveness of Norpace in children have not been established.* ***Adverse Reactions:*** *Dry mouth, urinary hesitancy, constipation, blurred vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, nausea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general fatigue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, cardiac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, generalized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, insomnia, dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated creatinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic jaundice, and agranulocytosis, all three reversible, have been reported.* ***Dosage and Administration:*** *Dosage must be individualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg per day given in divided doses four times daily. The recommended dosage schedule for most adults is 150 mg every six hours. For patients less than 110 pounds (50 kg) the recommended dosage is 100 mg every six hours. If rapid control of arrhythmia is essential, an initial loading dose of 300 mg of Norpace (200 mg for patients less than 110 pounds) is recommended. For patients with cardiomyopathy or possible cardiac decompensation, a loading dose should not be given and the initial dose limited to 100 mg every six hours, with subsequent dosage adjustments made gradually with close monitoring.* ***See current complete prescribing information for dosage recommendations. How Supplied:*** *Capsules containing 100 mg or 150 mg of disopyramide base.*

SEARLE *Searle Laboratories*
Division of Searle Pharmaceuticals Inc.
Box 5110, Chicago, Illinois 60680

The answer is....

Norpace® (disopyramide phosphate)

*in specific ventricular arrhythmias**

Efficacy comparable with quinidine

Proved with Holter recordings in double-blind clinical trials

More compatible with digoxin

Norpace, unlike quinidine, does not cause elevation of serum digoxin levels[2]

Better tolerated than quinidine

One fourth the dropout rate vs quinidine in double-blind clinical trials

Outstanding patient acceptance

- *Easily individualized dosing*
- *Usually well tolerated – even during long-term administration*

As with any antiarrhythmic drug, serious adverse reactions may occur in patients taking Norpace. Please see the facing page for a brief summary of prescribing information.

Quinton

INTRODUCING STATUS 100

WITH AN IMAGINATION TO MATCH YOUR OWN

Status 1000, The ECG Monitor That Gives You Programmable Control Over Every Aspect Of The Stress Test.

Quinton's Status 1000 is the first ECG stress test system that lets you use your imagination to modify or reprogram at will the various elements of a stress test.

Not just treadmill protocol, but lead selection, ST sample point, recorder speed, patient name, final report content and length, blood pressure prompting, etc. Everything is in your control like it should be.

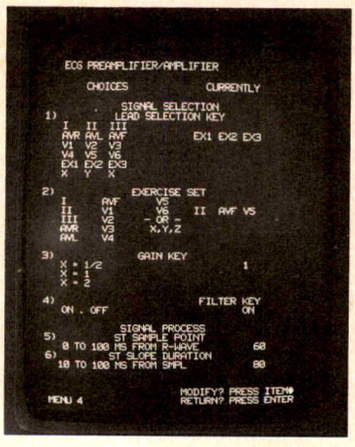
Use your professional imagination to create and program customized test procedures for pediatric, research, post-M.I., rehab., or out-patient situations.

Each physician in your institution can have their own preferred test procedure stored in memory.

With the Status 1000 you and your colleagues can customize test procedures based on the requirements of the patient, not the restrictions of the ECG system.

How The Sophisticated Status 1000 Makes Test Flexibility So Complete And Easy

With The Status 1000, Quinton introduces a new term, the "Stress Test Environment". It consists of 16 test elements. Each element, such as exercise lead set, or final report content, has parameters which you can establish or modify to suit your needs.



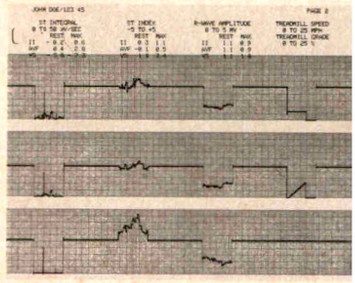
Yet, programming the Status 1000 is as easy as operating a pocket calculator, so special training is not required.

Comprehensive Data, Professionally Presented

In a single glance you see three channels of diagnostic quality ECG, averaged beats (both resting and current), heartrate, computed parameters, trend displays, stage number, stage time and elapsed time.

Plus, any abnormal beat will be instantly highlighted on the screen, then recorded and labeled automatically.

Your control extends to test reports, too. Printouts during the test may include averaged beats, rhythm strips, or full 12-leads. Final reports may include a wide variety of information. And each report is automatically labeled with pertinent data. Good bye work sheet.



Stay Ahead With The Status 1000

Because of the Status 1000's unparalleled flexibility and microprocessor technology its susceptibility to obsolescence is far less than other systems. And that makes it a good investment for you and your institution. Call Quinton toll free at 1-800-426-0538.

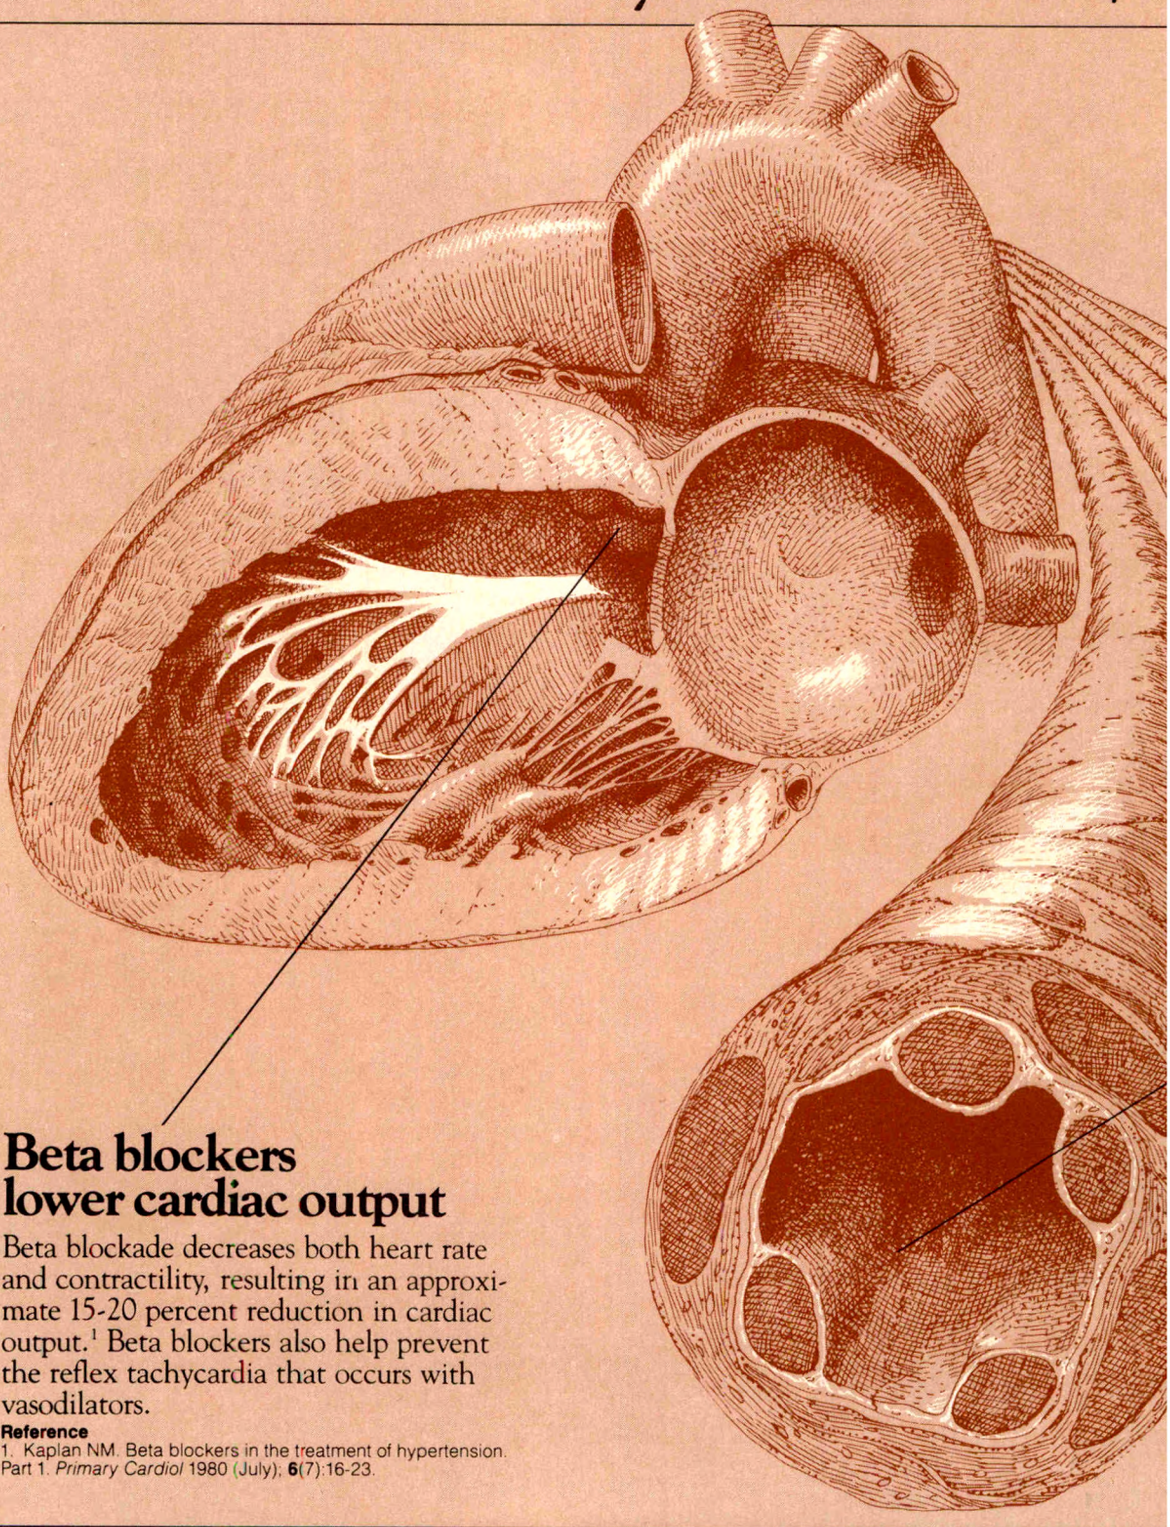
·After a diuretic...

Apresoline
hydralazine



Beta blockers lower cardiac output

Beta blockade decreases both heart rate and contractility, resulting in an approximate 15-20 percent reduction in cardiac output.[1] Beta blockers also help prevent the reflex tachycardia that occurs with vasodilators.

Reference

1. Kaplan NM. Beta blockers in the treatment of hypertension. Part 1. *Primary Cardiol* 1980 (July); **6**(7):16-23.

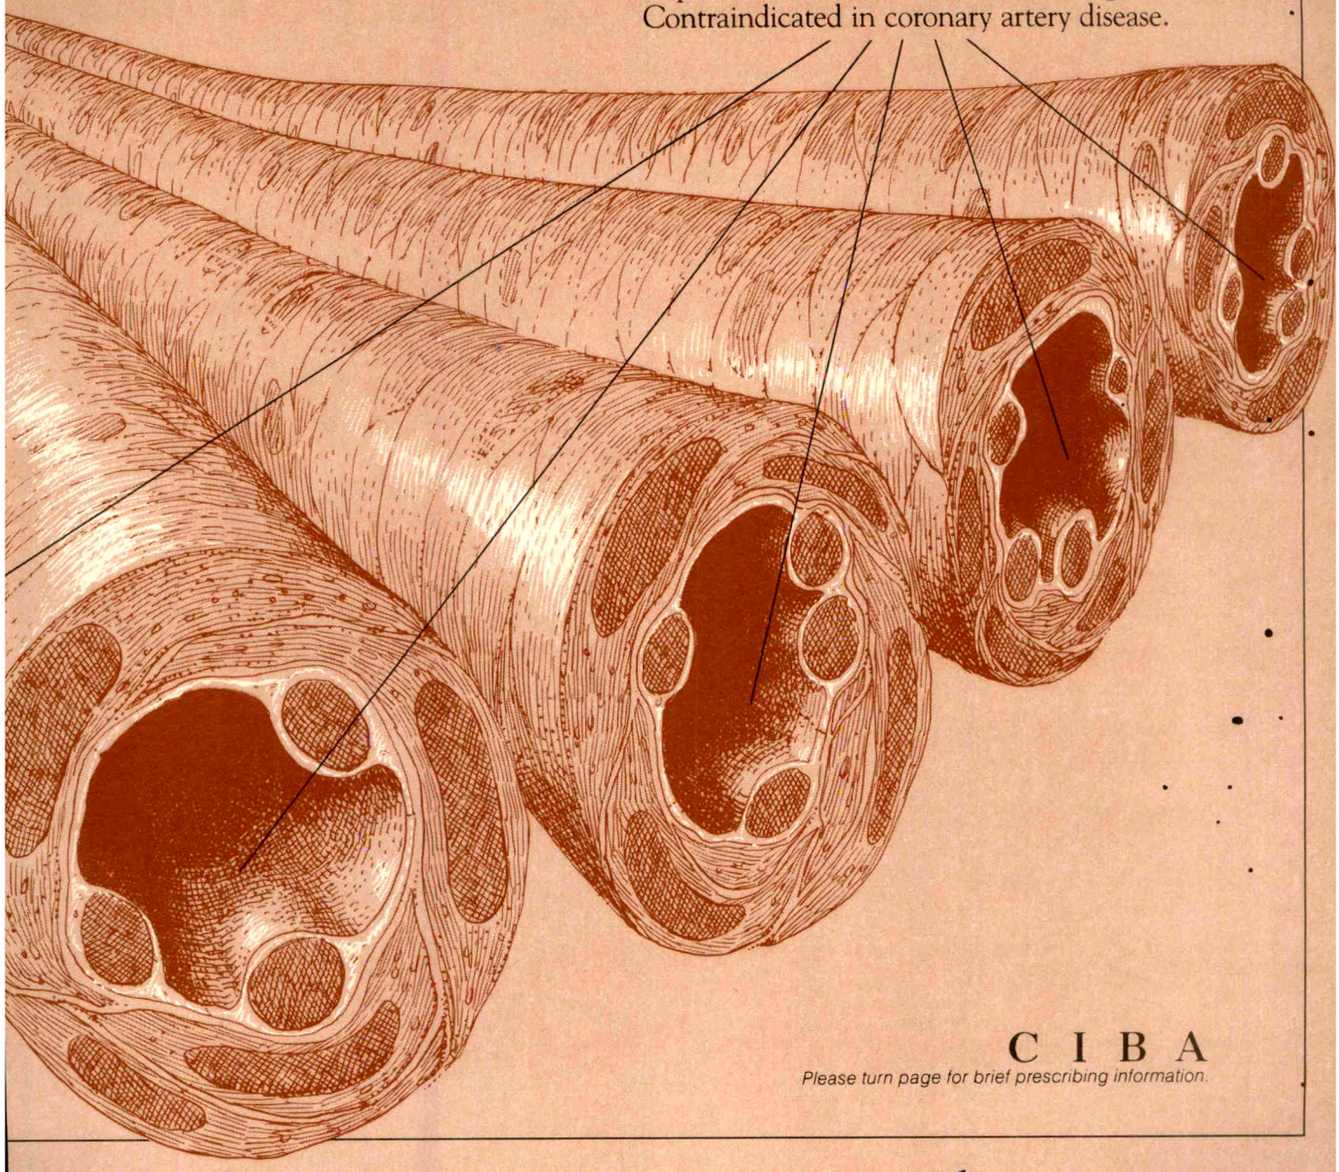
Where today's action is ir

Is the beta blockers

Apresoline lowers peripheral resistance

By relaxing smooth muscles in the walls of peripheral arterioles—an effect lacking in a beta blocker—Apresoline acts to lower elevated peripheral resistance.

As with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage. Contraindicated in coronary artery disease.



CIBA

Please turn page for brief prescribing information.

antihypertensive therapy

Apresoline® hydrochloride
hydralazine hydrochloride USP
TABLETS
INDICATIONS
Essential hypertension, alone or as an adjunct.
CONTRAINDICATIONS
Hypersensitivity to hydralazine; coronary artery disease; and mitral valvular rheumatic heart disease.
WARNINGS
Hydralazine may produce in a few patients a clinical picture simulating systemic lupus erythematosus. In such patients hydralazine should be discontinued unless the benefit-to-risk determination requires continued antihypertensive therapy with this drug. Symptoms and signs usually regress when the drug is discontinued but residua have been detected many years later. Long-term treatment with steroids may be necessary. Complete blood counts, L.E. cell preparations, and antinuclear antibody titer determinations are indicated before and periodically during prolonged therapy with hydralazine even though the patient is asymptomatic. These studies are also indicated if the patient develops arthralgia, fever, chest pain, continued malaise or other unexplained signs or symptoms. A positive antinuclear antibody titer and/or positive L.E. cell reaction requires that the physician carefully weigh the implications of the test results against the benefits to be derived from antihypertensive therapy with hydralazine.
Use MAO inhibitors with caution in patients receiving hydralazine.
When other potent parenteral antihypertensive drugs, such as diazoxide, are used in combination with hydralazine, patients should be continuously observed for several hours for any excessive fall in blood pressure.
Profound hypotensive episodes may occur when diazoxide injection and Apresoline (hydralazine hydrochloride) are used concomitantly.
Usage in Pregnancy
Animal studies indicate that hydralazine is teratogenic in mice, possibly in rabbits, and not in rats. Teratogenic effects observed were cleft palate and malformations of facial and cranial bones. Although clinical experience does not include any positive evidence of adverse effects on the human fetus, hydralazine should not be used during pregnancy unless the expected benefit clearly justifies the potential risk to the fetus.
PRECAUTIONS
Myocardial stimulation produced by Apresoline can cause anginal attacks and ECG changes of myocardial ischemia. The drug has been implicated in the production of myocardial infarction. It must, therefore, be used with caution in patients with suspected coronary artery disease. The "hyperdynamic" circulation caused by Apresoline may accentuate specific cardiovascular inadequacies. An example is that Apresoline may increase pulmonary artery pressure in patients with mitral valvular disease. The drug may reduce the pressor responses to epinephrine. Postural hypotension may result from Apresoline, but is less common than with ganglionic blocking agents. Use with caution in patients with cerebral vascular accidents.
In hypertensive patients with normal kidneys who are treated with Apresoline, there is evidence of increased renal blood flow and a maintenance of glomerular filtration rate. In some instances improved renal function has been noted where control values were below normal prior to Apresoline administration. However, as with any antihypertensive agent, Apresoline should be used with caution in patients with advanced renal damage.
Peripheral neuritis, evidenced by paresthesias, numbness, and tingling, has been observed. Published evidence suggests an antipyridoxine effect and the addition of pyridoxine to the regimen if symptoms develop. Blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura, have been reported. If such abnormalities develop, discontinue therapy. Periodic blood counts are advised during prolonged therapy.
The Apresoline tablets (10 and 100 mg) contain FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.
ADVERSE REACTIONS
Adverse reactions with Apresoline are usually reversible when dosage is reduced. However, in some cases it may be necessary to discontinue the drug.
Common: Headache; palpitations; anorexia; nausea; vomiting; diarrhea; tachycardia; angina pectoris.
Less frequent: Nasal congestion; flushing ; lacrimation; conjunctivitis; peripheral neuritis, evidenced by paresthesias, numbness, and tingling; edema; dizziness; tremors; muscle cramps; psychotic reactions characterized by depression, disorientation, or anxiety; hypersensitivity (including rash, urticaria, pruritus, fever, chills, arthralgia, eosinophilia, and, rarely, hepatitis); constipation; difficulty in micturition; dyspnea; paralytic ileus; lymphadenopathy; splenomegaly; blood dyscrasias, consisting of reduction in hemoglobin and red cell count, leukopenia, agranulocytosis, and purpura; hypotension; paradoxical pressor response.
DOSAGE AND ADMINISTRATION
Initiate therapy in gradually increasing dosages; adjust according to individual response. Start with 10 mg 4 times daily for the first 2 to 4 days, increase to 25 mg 4 times daily for balance of first week. For second and subsequent weeks, increase dosage to 50 mg 4 times daily. For maintenance, adjust dosage to lowest effective levels.
The incidence of toxic reactions, particularly the L.E. cell syndrome, is high in the group of patients receiving large doses of Apresoline. In a few resistant patients, up to 300 mg Apresoline daily may be required for a significant antihypertensive effect. In such cases, a lower dosage of Apresoline combined with a thiazide, reserpine, or both may be considered. However, when combining therapy, individual titration is essential to insure the lowest possible therapeutic dose of each drug.

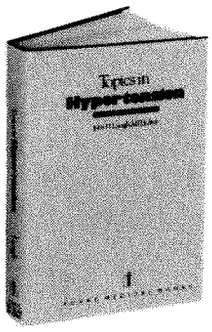
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by
John H. Laragh, MD
Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $49.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

When it's a matter of
disturbed rhythm of the heart
SUSTAINED RELEASE
Procan™ SR
(PROCAINAMIDE
HYDROCHLORIDE TABLETS)
for selected cardiac dysrhythmias
administered half as often
as conventional oral procainamide
can be used concomitantly with digoxin without significant
change in digoxin serum levels[1]
q6h dosage maintains procainamide blood levels all day and all night
at steady-state, plasma levels demonstrated the bioequivalence of
Procan SR given q6h to that of an equal total daily dosage of conventional
procainamide given q3h[2]
Procan SR...the original
sustained release oral procainamide

See following page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE
Before prescribing, please see full prescribing information.
A Brief Summary follows:

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that, in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient re-evaluated because asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney diseases, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome. Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patient receiving maintenance procainamide therapy.

ADVERSE REACTIONS: Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS). Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride tablets) are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dosage of 50 mg/kg of body weight given at three-hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dosage of 0.5 g to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: N 0071-0202 Procan SR 250 mg. Each sustained-release tablet contains 250 mg procainamide hydrochloride. Available in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 10 tablets each).

N 0071-0204 Procan SR 500 mg. Each sustained-release, scored tablet contains 500 mg procainamide hydrochloride. Available in bottles of 100 tablets and in unit-dose packages of 100 (10 strips of 10 tablets each).

Extra-Adrenergic Mechanisms Responsible for the Effects of Glucose-Insulin-Potassium Solution on Vulnerability to Ventricular Fibrillation

WESLEY W. BROOKS, DSc*
RICHARD L. VERRIER, PhD, FACC
BERNARD LOWN, MD, FACC

Boston, Massachusetts

In 53 chloralose-anesthetized dogs, the actions of glucose (10 mg/kg per min), insulin (0.025 U/kg per min) and potassium (0.025 mEq/kg per min) on the ventricular fibrillation and repetitive extrasystole thresholds were examined. Measurements were initially made in the control state and then repeated at 30, 60 and 120 minutes of infusion of glucose-insulin-potassium solution at a constant rate of 1.23 ml/min. The dogs received on the average 36 g of glucose, 44 U of insulin and 44 mEq of potassium over a 2 hour period. In the nonischemic myocardium, the infusion raised the threshold for ventricular fibrillation and repetitive extrasystole to a peak of 94 and 61 percent, respectively, without significantly changing serum potassium or circulating catecholamine concentration. In the ischemic myocardium, the incidence of spontaneous ventricular fibrillation during 10 minutes of coronary occlusion was reduced from 83 percent in the control state to 17 percent with glucose-insulin-potassium infusion. However, the infusion did not alter the incidence of ventricular fibrillation associated with reperfusion.

Because cardio-cardiac sympathetic reflexes are elicited in response to coronary occlusion, the effect of glucose-insulin-potassium infusion on ventricular vulnerability during left stellate ganglion stimulation and norepinephrine infusion was investigated. The infusion completely prevented the reduction in the vulnerable period threshold during stellate stimulation and norepinephrine infusion. Furthermore, the peak protection afforded by the infusion was greater than that achieved with beta adrenergic blockade and was still present in catecholamine-depleted hearts.

It is concluded that infusion of glucose-insulin-potassium solution protects against ventricular fibrillation in the normal and ischemic canine heart but not during reperfusion. This protection may be due in part to antagonism of adrenergic activity; however, the primary influence of the solution is mediated by extra-adrenergic mechanism.

From the Cardiovascular Research Laboratories, Department of Nutrition, Harvard School of Public Health, and Department of Medicine, Harvard Medical School, Boston, Massachusetts. This study was supported in part by Grant MH-2184 from the National Institute of Mental Health and Grant HL-07776 from the National Heart, Lung, and Blood Institute, National Institutes of Health, U.S. Public Health Service, Bethesda, Maryland. Manuscript received June 9, 1980; revised manuscript received July 26, 1980, accepted September 9, 1980.

* This work was performed during tenure of a Vittorio deNora/Diamond Schamrock Corporation fellowship.

Address for reprints: Bernard Lown, MD, Cardiovascular Research Laboratories, Department of Nutrition, Harvard School of Public Health, 665 Huntington Avenue, Boston, Massachusetts 02115.

In 1957, Cherbakoff et al.[1] showed that infusion of insulin and glucose prevented ventricular arrhythmias and fibrillation in experimental animals subjected to myocardial infarction. This finding was confirmed by Sodi-Pallares et al.,[2] who demonstrated diminished excitability of the ischemic myocardium after treatment with glucose-insulin-potassium solution. This therapy has received widespread clinical application for the prevention of ventricular arrhythmias after acute myocardial infarction.[2–6] However, the mechanism by which the solution affects cardiac electrical properties remains poorly defined. The protective effect of the solution has been ascribed to reduced potassium efflux from ischemic myocardial cells.[1,7] But insulin has been shown to protect the normal canine heart against ventricular fibrillation when shifts in extracellular potassium were prevented.[8] Hiatt et al.,[9] using pharmacologic doses of insulin, demonstrated a protective effect against ventricular

arrhythmias in dogs subjected to ligating the left circumflex coronary artery. They attributed this beneficial result to insulin blocking the action of catecholamines.[10]

The present study was undertaken to determine whether the action of glucose-insulin-potassium solution protects against fibrillation ensuing from coronary arterial occlusion as well as from reperfusion. There is evidence indicating that the former but not the latter is neurally mediated.[11,12] A further objective was to define the interaction between sympathetic neural activity and glucose-insulin-potassium solution as related to the salutary action of this solution on ventricular vulnerability to fibrillation.

Methods

Experimental preparation: Fifty-three healthy mongrel dogs of either sex, weighing 10 to 20 kg, were utilized. They were anesthetized with intravenous alpha chloralose (100 mg/kg, Sigma Chemical 10 percent weight in volume) and additional increments of 50 mg/kg were given when required to maintain a constant level of anesthesia. The animals were ventilated with a mixture of room air and 100 percent oxygen through a cuffed endotracheal tube using a Harvard respirator resulting in a concentration of 40 percent oxygen. Arterial oxygen tension was kept between 100 and 125 mm Hg and arterial pH between 7.35 and 7.45. A polyethylene catheter inserted into a femoral artery was used for sampling arterial blood and for monitoring blood pressure by means of a Statham P23Db transducer.

Cardiac Testing

Electrical testing of the heart was begun 30 minutes after induction of anesthesia and was accomplished by means of an intracavitary lead system consisting of a transvenous bipolar pacing catheter (Medtronic 5819 platinum electrodes with an interelectrode distance of 1.5 cm [width 3 mm] and electrocardiographic recording probe (USCI® semi-floating probe 003992-4F). The recording catheter terminated 20 mm proximally to the pacing catheter. The catheter system was positioned under fluoroscopic control at the apex of the right ventricle by way of a jugular vein. A Medtronic pacemaker was employed to deliver rectangular pulses of 2 ms duration at intervals of 300 ms. This rate (200 beats/min) was maintained constant during all determinations. The pacemaker current was adjusted to twice the mid diastolic threshold. The distal pole of the pacemaker catheter was made cathodal. Testing impulses of 5 ms duration were generated using a constant current Grass S44 square wave pulse generator (±1 percent current and its time accuracy) with an electrically isolated output and delivered through the bipolar pacing catheter. The pulse generator was equipped with appropriate circuitry to inhibit the output of the pacemaker for 1.5 seconds after delivery of the test stimulus, which occurred after every 12 to 15 paced beats.

Determination of the repetitive extrasystole and ventricular fibrillation thresholds: Measurement of the vulnerable period threshold was performed as follows: Electrical diastole was scanned by means of a test stimulus of 5 ms duration and an initial current of 8 mA. The scanning was conducted at 5 ms increments, beginning at the border of the absolute refractory period and ending at the apex of the T wave.[13,14] If no repetitive extrasystoles were induced, the stimulus intensity was increased in 2 mA steps and scanning was continued until repetitive extrasystoles were elicited. The lowest stimulus intensity that evoked repetitive ventricular responses in two of three trials defined the repetitive extrasystole threshold. Thereafter, the vulnerable period was scanned to define the ventricular fibrillation threshold. These determinations were made before and after each experimental intervention.

Defibrillation was accomplished, usually within 3 to 5 seconds, with a direct current pulse (100 to 200 watt-s capacitor discharge from a Lown cardioverter) delivered through a pair of copper plates (150 cm^2) previously fastened across the thorax.

Experimental Interventions

Glucose-insulin-potassium infusions: The dogs received 148 ml of a solution of glucose, insulin and potassium administered intravenously for 2 hours at a rate of 10 mg/kg body weight per min for glucose, 0.025 U/kg per min for insulin and 0.025 mEq/kg per min for potassium. Thus, a total of 36 g of glucose, 44 U of insulin and 44 mEq of potassium was administered to the treated animals, which weighed an average of 15 kg. Electrical testing was performed in the control state as well as at 30 minutes and 1 and 2 hours after the onset of the infusions. Serum potassium and glucose concentrations were determined at the time of electrical testing. In addition, circulating catecholamines were measured in response to glucose-insulin-potassium infusion according to a single isotope radioenzyme assay.[15]

Influence of glucose-insulin-potassium infusion on incidence of ventricular fibrillation during myocardial ischemia and reperfusion: The dogs were anesthetized with alpha-chloralose and fitted with instruments as described. A thoracotomy was performed through the fourth left intercostal space and the heart exposed after a pericardiectomy. The origins of the left anterior descending and circumflex coronary arteries were dissected. A snare of 2-0 silk suture was placed around either artery as close to its origin as possible.

The incidence of ventricular fibrillation after a 10 minute period of occlusion and subsequent reperfusion of either the left anterior descending or left circumflex coronary artery was recorded. The heart rate was maintained constant at 200 beats/min by ventricular pacing. The dogs were randomly assigned to either a control group or a glucose-insulin-potassium pretreatment group. In the latter group, infusion was begun 60 minutes before coronary occlusion and was terminated 2 minutes after reperfusion.

Effect of glucose-insulin-potassium on vulnerability induced by adrenergic stimulation: stellate ganglion stimulation: Stellate stimulation was accomplished with stimuli of 5 to 15 V, 5 ms duration and 10 hertz delivered to the main body of the decentralized ganglion. In these experiments, the cervical vagi were sectioned bilaterally and the contralateral stellate ganglion was removed. Thus, the direct effects of unilateral stimulation could be observed without activating the contralateral ganglion. A 15 minute rest period was allowed before cardiac electrical testing was begun. The effects of stellate ganglion stimulation on the repetitive extrasystole and ventricular fibrillation thresholds were studied with and without infusion of glucose-insulin-potassium solution beginning 60 minutes before stellate ganglion stimulation.

Pharmacologic Interventions

Norepinephrine infusion: Norepinephrine bitartrate (Levophed®, Winthrop) in normal saline solution was infused intravenously at a rate of 0.5 μg (base)/kg per min. This agent was administered for a period of 15 minutes before the effect of norepinephrine on the repetitive extrasystole and ven-

tricular fibrillation thresholds was tested. This dose of norepinephrine increases vulnerability to fibrillation without significantly altering mean arterial blood pressure. The threshold values during norepinephrine infusion were determined at 15 and 30 minutes after the start of infusion.

In a second group of dogs, glucose-insulin-potassium was administered intravenously at a rate of 10.00 mg/kg per min for glucose, 0.025 U/kg per min for insulin and 0.025 mEq/kg per min for potassium. Norepinephrine was added to this stock solution at a concentration that resulted in an infusion rate of 0.5 μg (base)/kg per min. The effects of concurrent administration of norepinephrine and glucose-insulin-potassium were examined 15 and 30 minutes after infusion.

Beta adrenergic blockade: Six dogs were subjected to beta adrenoceptor blockade using a single intravenous dose of propranolol (0.25 mg/kg Inderal®, Ayerst). This dose produces a high degree of blockade without altering myocardial membrane stability.[16]

Catecholamine depletion: Depletion of myocardial catecholamine stores was accomplished in 5 dogs by an intramuscular injection of 0.3 mg/kg of reserpine on 2 consecutive days before definitive study. This dose of reserpine reduces tissue stores of norepinephrine to chemically undetectable levels.[17]

Statistical analysis: The results were analyzed using Student's *t* test for paired and unpaired data. The criterion of significance was a probability (p) level of <0.05.

Results

Effect of glucose-insulin-potassium infusion in normal dogs: Administration of glucose, insulin and potassium resulted in an increase in fibrillation threshold in six dogs from a mean control value (± standard error of the mean) of 31 ± 4 to 48 ± 6 mA after 30 minutes ($p < 0.01$), 48 ± 3 mA after 1 hour and 60 ± 8 mA after 2 hours of infusion (Fig. 1). The threshold for inducing repetitive ventricular responses likewise increased from 23 ± 3 to 31 ± 5 mA after 30 minutes ($p < 0.05$), 33 ± 3 mA after 1 hour and 37 ± 3 mA after 2 hours of infusion. Plasma potassium concentration was not significantly altered but did tend to rise from control levels of 2.95 ± 0.21 to 3.25 ± 0.21 mEq/liter. The plasma glucose level increased from 89 ± 4 to 209 ± 22 mg/100 ml at the end of 2 hours of glucose-insulin-potassium infusion ($p < 0.001$). No correlation was evident between the magnitude of changes in plasma glucose concentration and the extent of change in the repetitive extrasystole and ventricular fibrillation thresholds.

Infusion of glucose-insulin-potassium resulted in a significant decrease in intrinsic heart rate from a control value of 148 ± 12 to 122 ± 10 beats/min after 1 hour and 118 ± 7 beats/min after 2 hours ($p < 0.01$) (Fig. 1). Mean arterial blood pressure did not significantly change. Serum concentrations of circulating catecholamines tended to decrease with glucose-insulin-potassium infusion, but were not significantly lower than control levels at the end of 2 hours (epinephrine 63 ± 30 to 29 ± 10 pg/ml and norepinephrine 216 ± 35 to 204 ± 29 pg/ml).

Effect of glucose-insulin-potassium on vulnerability during myocardial ischemia and reperfusion: Glucose-insulin-potassium infusion-induced protection against ventricular fibrillation was studied

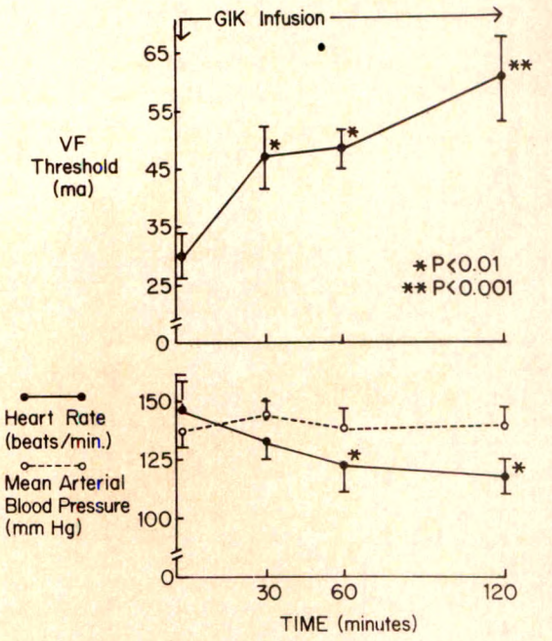

FIGURE 1. Effect of glucose-insulin-potassium (GIK) infusion on heart rate, arterial blood pressure and ventricular fibrillation (VF) threshold in six normal dogs. The infusion produced a moderate decrease in heart rate, did not alter mean arterial blood pressure and resulted in a significant increase in ventricular fibrillation threshold. P = probability.

in 24 dogs after 10 minutes of occlusion of either the left anterior descending or left circumflex coronary artery. In a group of 6 dogs, glucose-insulin-potassium infusion was begun 60 minutes before occlusion of the circumflex coronary artery. During control occlusion, five (83 percent) of six dogs manifested ventricular fibrillation, whereas after glucose-insulin-potassium infusion, only 1 of 6 dogs demonstrated this arrhythmia ($p < 0.01$). However, pretreatment with glucose-insulin-potassium did not decrease the incidence of ventricular fibrillation during release-reperfusion in animals subjected to left anterior descending coronary arterial occlusion (Fig. 2).

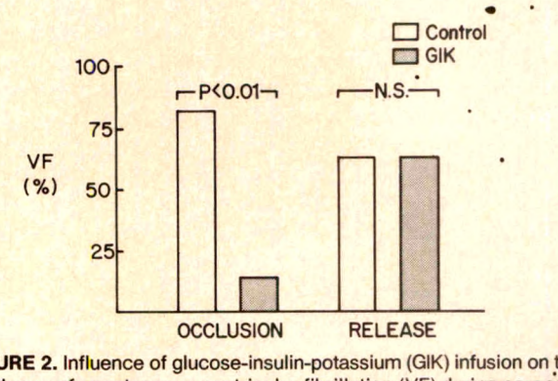

FIGURE 2. Influence of glucose-insulin-potassium (GIK) infusion on the incidence of spontaneous ventricular fibrillation (VF) during coronary arterial occlusion and release. The infusion provided significant protection against ventricular fibrillation during occlusion of the left circumflex coronary artery, but did not protect with release of occlusion of the left anterior descending coronary artery. N.S. = not significant.

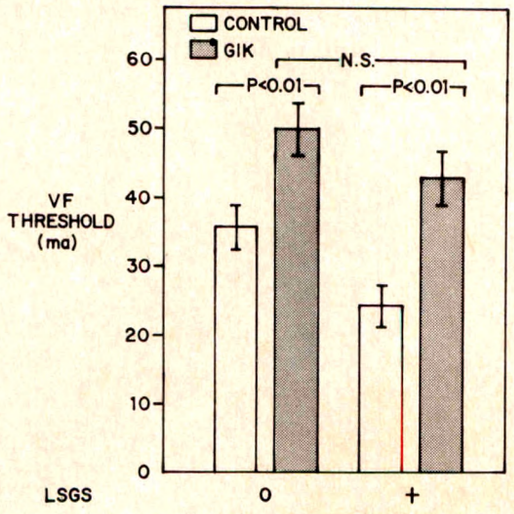

FIGURE 3. Effect of glucose-insulin-potassium (GIK) infusion on ventricular fibrillation (VF) threshold during sympathetic neural stimulation. In vagotomized dogs with stellate ganglia decentralized, left stellate ganglion stimulation (LSGS) (+) decreased the ventricular fibrillation threshold from 36 to 24 mA (33 percent [$p < 0.01$]). Glucose-insulin-potassium infusion during concurrent stellate ganglion excitation (+) prevented this change in ventricular fibrillation threshold.

Influence of glucose-insulin-potassium on vulnerability induced by adrenergic stimulation: Left stellate ganglion stimulation in six dogs resulted in a significant reduction in both the repetitive extrasystole threshold (from 21 ± 2 to 14 ± 2 mA, $p < 0.05$) and the ventricular fibrillation threshold (from 36 ± 2 to 24 ± 4 mA, $p < 0.01$). Glucose-insulin-potassium infusion for 60 minutes raised the baseline ventricular fibrillation threshold (from 36 ± 2 to 52 ± 6 mA, $p < 0.05$) and the repetitive extrasystole threshold (from 21 ± 2 to 28 ± 2 mA, $p < 0.05$). Moreover, the infusion, prevented the decrease in the ventricular fibrillation threshold and repetitive extrasystole threshold (from 28 ± 2 to 23 ± 4 mA, difference not significant) produced by sympathetic neural activation (Fig. 3).

The effect of norepinephrine infusion on the vulnerable period threshold was also substantially altered by administration of glucose-insulin-potassium infusion. Norepinephrine infusion in six dogs lowered both the repetitive extrasystole threshold (from 18 ± 2 to 11 ± 2 mA, $p < 0.05$) and the ventricular fibrillation threshold (from 28 ± 4 to 18 ± 2 mA, $p < 0.01$). Concurrent infusion of glucose-insulin-potassium solution for 30 minutes abolished the norepinephrine-induced reduction in the vulnerable period threshold (Fig. 4).

Beta adrenergic blockade: In six dogs, propranolol (0.25 mg/kg) resulted in a 29 percent increase in both the repetitive extrasystole threshold (from 21 ± 2 to 27 ± 3 mA, $p < 0.05$) and the ventricular fibrillation threshold (from 31 ± 3 to 40 ± 2 mA, $p < 0.01$). The magnitude of protection afforded by beta adrenergic blockade was significantly less than that provided by glucose-insulin-potassium infusion (Fig. 5). After administration of glucose-insulin-potassium to an additional group of six dogs, the repetitive extrasystole threshold increased by 61 percent ($p < 0.05$) and the ventricular fibrillation threshold by 94 percent at peak effect.

Effect of glucose-insulin-potassium on ventricular fibrillation threshold in dogs pretreated with reserpine: In five dogs, pretreatment with reserpine (0.3 mg/kg) resulted in a repetitive extrasystole threshold of 26 ± 3 mA and a ventricular fibrillation threshold of 48 ± 6 mA. In these dogs, glucose-insulin-potassium administration increased the ventricular fibrillation threshold from 48 ± 6 to 74 ± 12 mA after 30 minutes ($p < 0.01$) and to 77 ± 13 mA after 1 hour and 72 ± 11 mA after 2 hours of infusion (Fig. 6). The threshold for inducing repetitive ventricular responses increased from 26 ± 3 to 33 ± 6 mA after 30 minutes ($p < 0.05$) and to 38 ± 2 mA after 1 hour and 42 ± 6 mA after 2 hours of glucose-insulin-potassium infusion.

Discussion

These results confirm previous observations demonstrating the potent effect of glucose-insulin-potassium infusion in raising the threshold for ventricular fibrillation in both the normal as well as the acutely ischemic heart. However, pretreatment with these agents did not protect the heart during reperfusion after a 10 minute period of coronary arterial occlusion. Glucose-insulin-potassium infusion prevented the decrease in the vulnerable period threshold produced by sympathetic neural or humoral stimulation. The salutary effect was more pronounced than that achieved by beta adrenoceptor blockade and was not annulled by depletion of cardiac catecholamines.

Mechanism of diminished susceptibility to ventricular fibrillation: The electrophysiologic mechanism whereby glucose-insulin-potassium solution diminishes cardiac susceptibility to ventricular fibrillation during acute coronary occlusion is undefined. The fact that the solution raises the fibrillation threshold in the normal dog as well as lessening the incidence of spon-

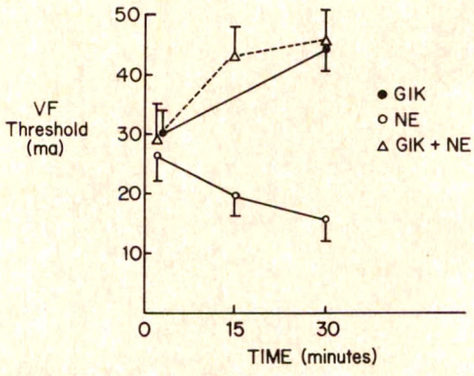

FIGURE 4. Effect of glucose-insulin-potassium (GIK) infusion on ventricular fibrillation (VF) threshold during sympathetic humoral stimulation. Norepinephrine (NE) infusion (0.5 μg/kg per min) for 30 minutes in neurally intact animals decreased the ventricular fibrillation threshold by 36 percent ($p < 0.01$). Glucose-insulin-potassium infusion during concurrent norepinephrine infusion increased the ventricular fibrillation threshold 53 percent above control value, to levels observed with glucose-insulin-potassium infusion alone.

taneous ventricular fibrillation after coronary occlusion suggests that the protection afforded may not depend on the presence of myocardial ischemia. The disparity of action of the solution on the malperfused and reperfused heart further emphasizes that disparate electrophysiologic mechanisms are implicated in these two conditions. Several diverse actions of the polarizing solution may account for the antifibrillatory effect noted during coronary occlusion. In the ischemic canine model, glucose-insulin-potassium administration reduces myocardial damage. This is indicated by the lessened S-T segment changes, decreased depletion of myocardial creatine kinase and glycogen, diminished electron microscopic changes,[18,19] improvement in hemodynamic function[20] and a decrease in ventricular arrhythmias.[1,7,21] Cherbakoff et al.[1] found that infusion of 400 ml of 50 percent dextrose in water plus 70 to 200 U of regular insulin for 2 hours prevented ventricular arrhythmias and delayed the onset of ventricular fibrillation in dogs subjected to acute ligation of the left circumflex coronary artery. However, ventricular vulnerability during reperfusion was not examined. The protective effect of glucose-insulin-potassium solution was ascribed to reduced potassium efflux from ischemic myocardial cells. Recently Obeid et al.[8] demonstrated a protective effect of glucose, insulin and potassium on vulnerability to ventricular fibrillation in the nonischemic dog myocardium. The heart was protected even when extracellular potassium was maintained at a low concentration by hemodialysis.

Role of reduced myocardial free fatty acid uptake: Glucose-insulin-potassium infusion has been shown to decrease circulating free fatty acid concentrations in both animals[22] and human beings.[6] The resultant decrease in myocardial free fatty acid uptake in response to the infusion has been postulated to be a basis for the therapeutic action on the ischemic heart.[2] Indeed, a recent report by Rogers et al.[6] demonstrated a reduction in premature ventricular complexes and ventricular tachycardia in acute myocardial infarction in patients treated with glucose-insulin-potassium infusion as compared with control subjects. Free fatty acid levels were significantly lowered in recipients of the infusion and were substantially lower in patients having a paucity of premature ventricular complexes.[6] Although free fatty acid concentration was not measured in our study, we can assume that, because similar concentrations of glucose, insulin and potassium were employed, the level of free fatty acids decreased. Thus a reduction in free fatty acid concentration should be considered a possible mechanism for the salutary action of glucose-insulin-potassium solution on vulnerability of the heart to fibrillation. Nevertheless, Ahmed et al.[2] found the beneficial effect of the solution on myocardial function to be unrelated to a reduction in the level of free fatty acids.

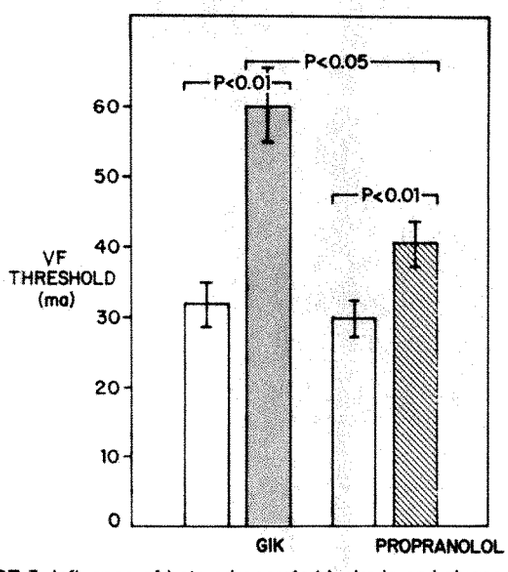

FIGURE 5. Influence of beta adrenergic blockade and glucose-insulin-potassium (GIK) infusion on the ventricular fibrillation (VF) threshold. Propranolol (0.25 mg/kg) administered in an intravenous bolus dose to six neurally intact dogs significantly raised the ventricular fibrillation threshold by 29 percent, whereas in another group of six dogs glucose-insulin-potassium infusion for 2 hours raised the threshold by 94 percent.

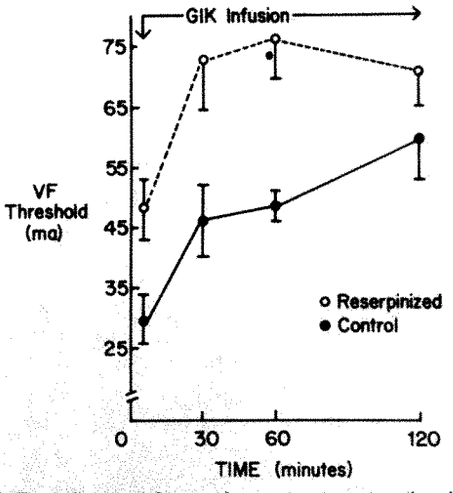

FIGURE 6. The influence of reserpine pretreatment on the changes in ventricular fibrillation (VF) threshold induced by glucose-insulin-potassium (GIK) infusion. In five dogs pretreated with reserpine (0.3 mg/kg), glucose-insulin-potassium administration further raised the ventricular fibrillation threshold.

Role of reduced profibrillatory effect of sympathetic neural and neurohumoral activities: Hiatt et al.[9] demonstrated that large doses of insulin and 10 percent dextrose in water had a protective effect against ventricular arrhythmias in dogs subject to circumflex coronary arterial ligation. They conjectured that the response was the consequence of insulin blocking the action of catecholamines. Such a mechanism was suggested from observations in nonischemic dogs in which insulin prevented arrhythmias induced by epinephrine and isoproterenol.[10] Our data demonstrate that glucose-insulin-potassium infusion indeed prevents the reduction in ventricular fibrillation threshold after norepinephrine administration or stellate ganglion stimulation. The similarity of results obtained with different experimental approaches for augmenting

adrenergic activity supports the hypothesis that the glucose-insulin-potassium solution antagonized the profibrillatory effect of sympathetic neural and neurohumoral activity. This view would also account for the protection the solution affords the ischemic myocardium because potent cardio-cardiac sympathetic reflexes are promptly elicited in response to coronary occlusion.[11,12] Our finding that glucose-insulin-potassium infusion also raised the ventricular fibrillation threshold in dogs treated with reserpine indicates that such a mechanism cannot fully account for the protective actions of the infusion. Furthermore, the magnitude of protection with the infusion was considerably greater than that resulting from beta adrenergic blockade. Rossi et al.[24] reported that glucose, insulin and potassium solution administered to patients was antiarrhythmic even after beta adrenergic blockade.

Direct electrophysiologic effects: In the study of Obeid et al.,[8] it was noted that glucose-insulin-potassium infusion prevented degeneration to ventricular fibrillation or, once ventricular fibrillation was present, caused spontaneous resumption of sinus rhythm. These animals were normal and without myocardial ischemia. Although the underlying mechanism was not elucidated, a direct electrophysiologic action of glucose-insulin-potassium solution on the heart seems plausible. Several studies have suggested that a "membrane" effect might be the major factor accounting for the action of the solution.[22,25,26]

Glucose administration promotes potassium uptake into the cell[21] and reduces potassium loss from ischemic myocardium,[27] resulting in hyperpolarization and improved local conduction velocity. This theoretically should reduce the incidence of so-called slow response potentials.[28] Insulin further enhances glucose uptake, resulting in greater hyperpolarization and further stabilizing the membrane potential.[29] Thus, these electrophysiologic responses to glucose-insulin-potassium solution could account for the enhanced electrical stability observed in ischemic as well as in nonischemic myocardium.

Lack of effect with coronary reperfusion: In contrast to its effects on vulnerability during occlusion, glucose-insulin-potassium administration did not alter the incidence of fibrillation with reperfusion. The mechanism whereby ventricular fibrillation is precipitated during reperfusion of ischemic myocardium remains uncertain. However, there is evidence that washout products of cell ischemia may be involved.[30] It has been demonstrated that if blood flow is gradually restored to the ischemic myocardium[31,32] or if perfusion is maintained with deoxygenated fluid, the incidence of ventricular arrhythmias on reinstitution of flow is reduced.[31–34] The finding that ventricular fibrillation ensues within seconds after reinstitution of coronary arterial flow also argues for washout of metabolic products.[30] Recently, Downar et al.[35] showed that "ischemic" blood obtained from local coronary veins during release of coronary occlusion in pigs exerts a potent depressant effect on excitability of even normal myocardium.

Thus, there is evidence that the release of blood constituents provide a potent stimuli for triggering ventricular fibrillation. Beta adrenergic blockade[36,37] or cardiac membrane stabilization with lidocaine[36] has proved ineffectual in preventing vulnerability during release. Because the influence of glucose-insulin-potassium solution on vulnerability derives from its antiadrenergic and membrane stabilizing effects, it is therefore not unanticipated that it did not protect during release-reperfusion.

Clinical considerations: The present findings are consistent with recently accumulating clinical evidence[6] indicating a substantial antiarrhythmic action of glucose-insulin-potassium solution. The protective effect appears to be partly due to the solution's antiadrenergic influence and partly to its cardiac membrane-stabilizing action. Because insulin is the primary component that alters ventricular vulnerability,[8] it is possible that changes in endogenous insulin levels may also influence ventricular electrical properties. This supposition is supported by our preliminary studies showing that intravenous administration of glucose in a dose comparable with that used in a standard glucose tolerance test significantly increases the vulnerable period threshold. The effects of glucose administration on vulnerability correlate with the changes in insulin blood levels and are completely prevented by blocking endogenous insulin secretion with diazoxide. The possibility that spontaneous fluctuations in insulin blood levels in response to physiologic and pathophysiologic states can influence vulnerability deserves further exploration.

Pretreatment with platelet-inhibitory doses of aspirin (3 mg/kg body weight) has been shown to augment epicardial collateral flow by more than 50 percent ($p < 0.05$) 4 hours after ligation of the left anterior descending coronary artery in dogs. To determine whether this favorable influence of aspirin is sufficient to decrease the amount of infarcted tissue, either intravenous aspirin, 3 mg/kg ($n = 17$), or saline solution ($n = 17$) was administered to dogs 10 minutes before occlusion of the left anterior descending coronary artery. Administration of saline solution or aspirin was repeated every 24 hours. By 72 hours, 5 dogs in each treatment group had died. Survivors were killed at 72 hours. The portion of the left ventricle at risk of infarction was delineated by perfusion of the aortic root with Evans blue and simultaneous perfusion of the distal left anterior descending coronary artery with saline solution under equal physiologic pressures. Slices of the stained heart were incubated with triphenyltetrazolium to identify gross infarct (with histologic confirmation). Total mass of left ventricle, myocardium at risk, and infarct size were measured in each dog. A direct relation was found between the mass at risk and the mass infarcted ($r = 0.84$, $p < 0.001$). Aspirin-treated dogs did not differ from control dogs in percent ventricle at risk (mean ± standard error 37 ± 2 versus 40 ± 2), percent infarct weight/left ventricle (29 ± 3 versus 31 ± 2) or percent infarct weight/weight of ventricle at risk (78 ± 4 versus 77 ± 3). Thus, despite aspirin's ability to inhibit platelet aggregation and to increase epicardial collateral flow by more than 50 percent, aspirin treatment failed to reduce infarct size in this dog model.

Platelets accumulate in the ischemic myocardium of both dogs and primates after experimental coronary arterial occlusion,[1,2] and aspirin has been shown to decrease platelet trapping in the periphery of ischemic myocardium in the dog.[1] Hence, aspirin and other platelet-inhibitory drugs might be beneficial during acute myocardial ischemia by preventing platelet-mediated vascular obstruction and by improving blood flow to the ischemic region. Compatible with this hypothesis are the findings that aspirin reduces electrocardiographic evidence (S-T segment elevation) of acute ischemia[1] and, when administered intravenously in platelet-inhibitory doses to dogs before coronary occlusion, increases epicardial collateral flow by more than 50 percent 4 hours after occlusion.[3] The current study was undertaken to determine whether this potentially beneficial increase in blood flow in dogs is associated with salvage of ischemic myocardium and reduction of infarct size.

Variability in the amount of myocardium lying within the distribution of canine coronary arteries results in significant variation in the mass of infarcted tissue within a group of dogs after coronary occlusion, even when care is taken to ligate the artery at the same anatomic site.[4] The effects of possible infarct-sparing agents on infarct size are thus difficult to assess. Hence, we employed a method to determine myocardial infarct mass relative to the mass of myocardium lying within the distal distribution of the occluded coronary artery, using postmortem staining techniques.

Methods

Experimental procedure: Thirty-four foxhounds of either sex, weighing 22 to 33 kg, were anesthetized with sodium thiamylal, halothane and nitrous oxide. The animals were intubated and artificially respired with room air. Heart rate and blood pressure were monitored. Under sterile operating conditions, the heart was exposed through a left thoracotomy, and the left anterior descending coronary artery was isolated from surrounding tissue.

Aspirin (*acetylsalicylic acid, U.S.P.*), 1.0 mg/ml, dissolved in a solution of saline and sodium bicarbonate at pH 7.4 to 7.5, was administered intravenously over a 2 minute period to 17 randomly chosen dogs in a dose of 3 mg/kg body weight. This intravenous dose of aspirin has previously been shown to fully inhibit in vitro adenosine disphosphate-induced aggregation of dog platelets and to increase epicardial collateral flow during acute ischemia.[5] Seventeen control dogs received intravenous saline solution, 3 ml/kg. Ten minutes after either aspirin or saline administration, the left anterior descending coronary artery was ligated at a point just distal to the first major diagonal coronary artery. Myocardial ischemia was verified by the immediate appearance of cyanotic, often dyskinetic, myocardium on the anterior surface of the heart in the distal distribution of the occluded artery. The thoracotomy was then closed, and anesthesia discontinued. During the next 3 days each dog received either intravenous aspirin, 3 mg/kg, or saline solution, 3 ml/kg, every 24 hours.

Five dogs in each treatment group died within 72 hours after occlusion. Of these, one dog treated with aspirin and two control dogs had ventricular tachycardia that progressed to ventricular fibrillation and died within the 1st hour after occlusion. The remaining seven dogs died between 24 and 60 hours after occlusion; autopsy studies in these animals demonstrated evidence of myocardial infarction in the distribution of the distal left anterior descending coronary artery and no other apparent cause of death. These 10 dogs are excluded from subsequent analysis.

Preparation of the heart: Seventy-two hours after occlusion, the 24 surviving dogs were given 10,000 units of heparin intravenously and killed with a lethal dose of sodium pentobarbital. The hearts were immediately excised and rinsed. To determine the region of distribution of the left anterior descending coronary artery distal to the occlusion, each isolated heart was suspended from the left and right atria by clamps that occluded all veins entering these chambers. A cannula with a diameter of 1.4 cm was inserted and secured into the aortic root, and another (diameter 1.2 mm) into the left anterior descending coronary artery immediately distal to the site of the initial occlusion (Fig. 1). The aortic root was then perfused with Evans blue solution (1 g/100 ml in saline solution) while the distal left anterior descending coronary artery was perfused with saline solution. Perfusion through both cannulas was performed simultaneously and under equal physiologic pressures (110 mm Hg) to prevent flow of dye from the nonischemic portion of the left ventricle to the ischemic myocardium by way of any collateral channels. Such collateral vessels might have existed before occlusion or developed after occlusion. Separate studies in our laboratory have shown that the decrease in pressure across the 1.2 mm cannula was small at low flow rates (less than 10 mm Hg at flow rates of less than 50 cc/min), so that the perfusion pressures at the tips of both cannulas were comparable.

The result of the myocardial staining procedure was the demarcation of two visually distinct regions of the heart (*Fig. 2A*). The Evans blue solution, perfused through the aortic root, stained all myocardium not supplied by the occluded

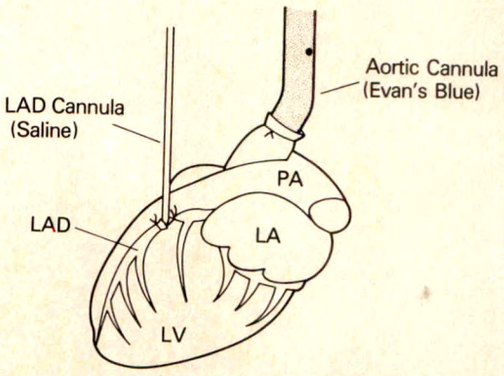

FIGURE 1. Cannulas positioned in the isolated heart for determining the region of distribution of the left anterior descending coronary artery (LAD) distal to the site of occlusion. The aortic cannula was perfused with Evans blue dye while the cannula in the left anterior descending coronary artery was perfused with saline solution. LA = left atrium; LV = left ventricle; PA = pulmonary artery.

portion of the left anterior descending coronary artery a deep blue. The myocardium supplied by this occluded artery, perfused with saline solution, remained unstained. Subsequent experience with fluorescein perfusion of the distal portion of this artery has confirmed that all ventricular myocardium not stained by Evans blue is perfused through the distal left anterior descending artery.[6] This unstained portion of the myocardium was considered potentially at risk of becoming ischemic after occlusion and therefore at risk of infarction. The cannulas were removed, the atria and great vessels were excised and the ventricles were sliced into six or seven parallel "bread-loaf" slices 1 cm thick, each perpendicular to the long axis of the left ventricle (Fig. 2, B and C). The right ventricular free wall of each slice was removed, and each remaining left ventricular slice was weighed and then incubated for 40 minutes in a 1 percent solution of triphenyltetrazolium chloride in phosphate buffer at 40° C by the method of Lie et al.[7] Triphenyltetrazolium staining (Fig. 2D)

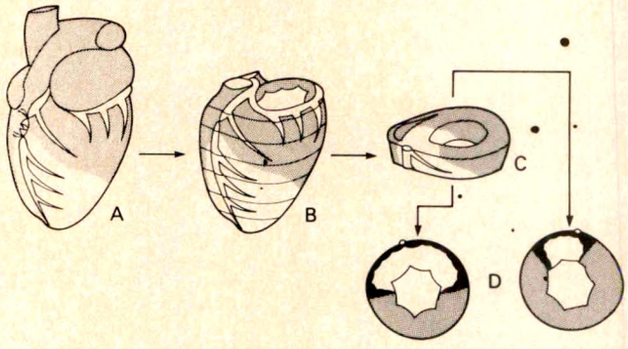

FIGURE 2. Determination of the mass of infarcted myocardium and myocardium at risk of infarction. **A,** result of Evans blue staining showing unstained myocardium "at risk" in the distribution of the left anterior descending coronary artery distal to occlusion. **Heavy stippling** identifies portions of myocardium stained blue. **B,** atria and great vessels removed and ventricles cut into parallel "bread-loaf" slices. **C,** typical mid ventricular bread-loaf slice. **D,** apical and basal surfaces of typical bread-loaf slice of cardiac ventricles after removal of right ventricular free wall and incubation with triphenyltetrazolium chloride. **Solid black areas** identify viable myocardium (stained red by tetrazolium) within the "risk" region.

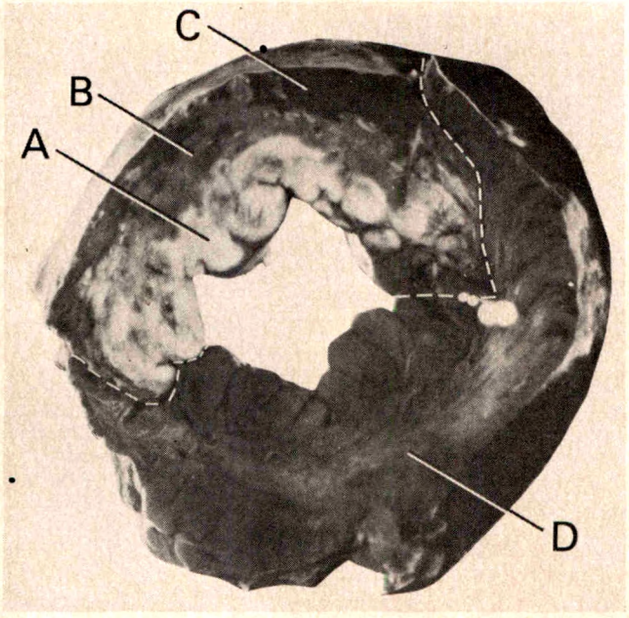

FIGURE 3. Apical surface of a typical bread-loaf slice of the left ventricle after tetrazolium staining (reproduced from a color slide). Within the region at risk, indicated by the area within the **dashed lines,** infarcted tissue is identified as a central white area (A) and a surrounding light pink-stained area (B). Viable myocardium is stained deep red (C). D = normal myocardium outside the region at risk.

discriminated infarcted (unstained and appearing white) from noninfarcted myocardium (stained deep red).[7,8]

Measurement of myocardial infarct size: Color photographs of both surfaces of each slice after incubation with tetrazolium revealed within the region of myocardium at risk three macroscopically distinct areas (Fig 3): a central white area surrounded by an irregular light pink-staining area and a peripheral dark red-staining area. Histologic examination of these areas demonstrated that the white and light pink-stained areas represented infarcted myocardium and that the red-stained area represented normal myocardium (Fig. 4). Normal myocardium within the region at risk, when present, always lay in the lateral and epicardial periphery of the risk region.

Color slides were obtained from both the apical surface and basal surface of each slice, projected onto paper, and traced. The areas of infarction and myocardium at risk for each surface were measured using a video planimetry system[9,10] and expressed as a percent of the total area of the surface. These percent values were averaged for the two surfaces and then multiplied by the mass of the slice to yield the mass of myocardium at risk and the mass of infarct for that slice. This procedure, performed for all six or seven slices and then summed, determined the total mass of the left ventricle, the mass of myocardium at risk of infarction and the mass of infarcted myocardium. The mass of infarcted myocardium was then expressed both as a percent of total left ventricular mass and as a percent of the mass of myocardium at risk of infarction.

Statistical methods: Data were analyzed with Student's *t* test (using paired and unpaired data) and linear regression analysis.

Results

Hemodynamics: Hemodynamic data before and 5 minutes after occlusion of the left anterior descending coronary artery in aspirin-treated dogs did not differ significantly from findings in control dogs (Table I). Paired analysis revealed no significant increase in heart rate after occlusion for either treatment group or for the entire study population. However, both groups had significant decreases in mean femoral arterial pressure after occlusion ($p < 0.05$), which persisted in most ani-

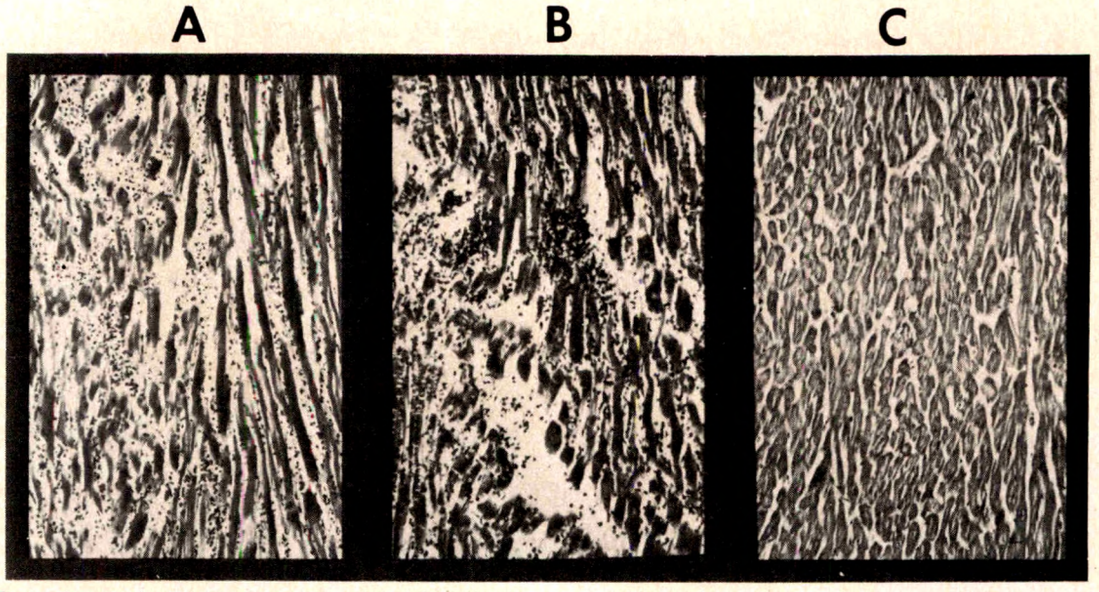

FIGURE 4. Photomicrographs of histologic sections taken from the three areas of the region at risk. **A,** section from white (unstained) area of the risk region corresponding to area A in Figure 3. Coagulation necrosis and polymorphonuclear cell infiltration indicate that this area is infarcted. **B,** section from light pink-stained myocardium corresponding to area B in Figure 3. There is again coagulation necrosis and polymorphonuclear infiltration indicating that this area is histologically identical to the white (unstained) area. **C,** section from deep red-stained myocardium shows normal histologic structure. (Hematoxylin-eosin ×50, reduced by 10 percent.)

mals until the termination of hemodynamic monitoring. Change in heart rate or blood pressure did not correlate with either the mass of infarcted tissue or the mass of myocardium supplied by the left anterior descending coronary artery distal to the occlusion (myocardium at risk), determined by the subsequent staining techniques.

Infarct size: The calculated myocardial infarct mass varied widely in both groups (0.9 to 66.4 g in aspirin-treated dogs and 0.5 to 60.1 g in control dogs) despite careful attempts to ligate the left anterior descending coronary artery at similar anatomic sites in all dogs. Infarct size correlated poorly with total left ventricular mass ($r = 0.14$), but showed excellent correlation with the myocardial mass at risk; infarct size, expressed as a percent of left ventricular mass (Fig. 5), was directly related to the size of the risk region ($r = 0.84$, $p < 0.001$). This was true in both the control group ($r = 0.87$, $p < 0.001$) and the aspirin-treated group ($r = 0.84$, $p < 0.001$). The linear regression equation derived from this relation suggested that dogs with a small region of risk (less than 20 percent of left ventricular mass) would not manifest a myocardial infarction after occlusion. Of the four dogs with a risk region of less than 30 percent of left ventricular mass, three had an infarct mass of less than 2 percent of the left ventricular mass.

A linear relation was not observed between infarcted myocardium and myocardium at risk (Fig. 6), when infarct size was expressed as a percent of the mass of the risk region ($r = 0.39$). Instead, a threshold relation existed, so that three of four dogs with a small risk region (less than 30 percent of the left ventricle) had virtually no infarct, whereas dogs with a larger region at risk (greater than 30 percent of the left ventricle) consistently had a larger infarct (62 to 96 percent) of the region at risks. Because risk regions of less than 30 percent of left ventricular mass would be anticipated to yield a low incidence rate of infarction, the four dogs with such a risk region were excluded from the final analysis. When these four dogs were excluded, the size of the risk region again did not correlate with the percent of the risk region with infarction ($r = 0.36$).

A beneficial effect of aspirin on myocardial infarct size (that is a smaller infarct size than the control value for any given mass of myocardium at risk) would shift the aspirin data points in Figures 5 and 6 in a downward direction. However, the relation between infarct size and risk region (Fig. 5) did not differ between the control and the aspirin-treated groups (slope 1.32 versus 1.74, difference not significant). Moreover, aspirin-treated dogs did not differ significantly from control dogs in total infarct size, infarct size relative to left ventricular mass or infarct size relative to myocardium at risk (Table II). When the four animals with a risk region of less than 30 percent of left ventricular mass were included in a repeated analysis, the findings were unchanged.

Discussion

Role of antiplatelet agents in experimental myocardial infarction: Platelet deposition has been demonstrated in ischemic myocardium during experi-

mental coronary arterial occlusion in both dogs and primates,[1,2] and pretreatment with aspirin reduces such platelet trapping.[1] Aspirin administration in dogs has also been shown to abolish completely spontaneous cyclic reductions in coronary flow that are associated with platelet aggregates after subtotal occlusion[11] and to reduce the extent of myocardial necrosis induced by epinephrine infusion, which also is associated with platelet aggregation.[12] Aspirin-induced reductions in S-T segment elevations[1] and in the incidence of ventricular fibrillation[13] have been reported in dogs after coronary occlusion. Moreover, aspirin increases collateral flow to the border of ischemic regions in baboons[14] and to the epicardial zone within the ischemic region 4 hours after occlusion of the left anterior descending coronary artery in dogs.[3,5] Finally, ibuprofen, whose effects are similar to those of aspirin in inhibiting prostaglandin synthesis and platelet aggregation, has recently been shown to reduce infarct size in dogs.[15,16]

However, the available evidence does not uniformly demonstrate a beneficial role of aspirin and other antiplatelet agents during acute myocardial ischemia. Ogletree and Lefer[17] found no decrease in either creatine kinase release or S-T segment elevation in cats pretreated with aspirin, and indomethacin was found in dogs to reduce collateral flow[18] and to increase S-T segment elevation[18] and infarct size.[19]

Our study was undertaken to resolve the ambiguities concerning the potential role of aspirin in reducing myocardial infarct size in a canine model of acute infarction. We chose to administer aspirin intravenously in a dose of 3 mg/kg. This dose has previously been shown to inhibit fully canine platelet aggregation and to augment significantly epicardial collateral flow after coronary occlusion; a larger dose (30 mg/kg) did not result in a further increase in collateral flow.[5]

Methodologic problems in determining infarct size: First, we sought to determine the feasibility of comparing infarct sizes in the canine heart. Meaningful quantitative comparison of myocardial infarct size from dog to dog is difficult because the wide variability in the anatomic distribution of the coronary arteries in this species results in considerable variation in the amount of tissue infarcted. Infarct mass in our series ranged from 0.5 to 66.4 g, despite attempts to ligate the left anterior descending coronary artery at a similar anatomic site in each animal. Correction for differences in left ventricular mass did not reduce this variation. Lowe et al.,[4] using in vitro intracoronary latex injections after occlusion of the left circumflex coronary artery, showed that the amount of myocardial necrosis correlates closely with size of the occluded coronary bed. Jugdutt et al.,[19] utilizing in vitro intracoronary injection of barium to define angiographically the distal coronary bed "risk region" 48 hours after occlusion of the left circumflex artery, also noted an excellent correlation between infarct mass and mass of the risk region.

To delineate the myocardium within the distribution of the left anterior descending coronary artery distal to occlusion in our series, Evans blue dye was delivered to the myocardium by way of the aortic root and saline solution was infused, simultaneously and under equal physiologic pressures, at a site just distal to the site of occlusion. The unstained myocardium thus represented the "region at risk" and the myocardium stained blue represented that portion of the heart perfused by vessels unaffected by the occluded artery. The unstained risk region was then "counterstained" by incubation in triphenyltetrazolium chloride, to identify macroscopically the infarcted portion of the risk region. The presence of normal or infarcted myocardium was then confirmed histologically.

Left anterior descending coronary risk regions determined with our method (40 ± 1 percent of the left ventricle) were comparable with the left circumflex coronary risk regions of Lowe et al.[4] and Jugdutt et al.[19] (42 ± 1 percent and 43 ± 4 percent, respectively). However, infarct size in our control dogs was considerably greater (31 ± 2 percent of the left ventricle in our series versus 15 ± 1 percent and 14 ± 2 percent in theirs). These differences may represent methodologic differences from our open chest coronary occlusion technique (Lowe et al. used a coronary arterial reperfusion model, and Jugdutt et al. performed coronary occlusions in closed chest animals), or differences in the in vitro demarcation of the regions at risk. Alternatively, these disparate results may reflect differences in the properties of collateral circulation within the distal left anterior descending and left circumflex coronary arterial beds of the dog. Infarct size (28 ± 2 percent of the left ventricle) in the control group studied by Ribeiro

et al., who utilized occlusion of the left anterior descending artery in open chest dogs,[15] was quite similar to that in our series.

Despite these differences, we found an excellent correlation between infarct mass and mass of the distal left anterior descending coronary risk region, either when both variables were expressed as absolute mass ($r = 0.86$) or when both were expressed as a percent of total left ventricular mass ($r = 0.84$, Fig. 5). From our linear regression equation, risk regions of 20 percent or less of left ventricular mass would be anticipated to contain no infarct. This observation was previously suggested by extrapolation of the data in models of occlusion of the left circumflex coronary artery.[4,19] Our actual data demonstrated that three of four dogs in our series with a risk region of less than 30 percent of left ventricular mass had only tiny islands of infarcted tissue by tetrazolium staining, confirmed histologically, that constituted 0.2 to 1.5 percent of the left ventricle. Presumably, the potential for collateralization of small regions of risk is sufficient to prevent extensive infarction. Aside from these three dogs with a small region of risk, the percent of infarcted muscle within the risk region was extensive, and ranged from 62 to 96 percent.

Explanation for lack of beneficial effect of aspirin on infarct size: Because of the good correlation between infarct mass and mass of myocardium at risk, we believed that this canine model of acute myocardial infarction provided an excellent means of determining whether a given agent can modify infarct size. Our results failed to demonstrate a beneficial effect of aspirin in reducing infarct size (Fig. 5, Table II). The lack of effect of aspirin on overall infarct size is compatible with data demonstrating no decrease in either creatine kinase release or S-T segment elevation in cats treated with oral aspirin (50 mg/kg) before ligation of the left anterior descending coronary artery.[17]

Several explanations may contribute to this lack of beneficial effect. The dose of aspirin we used, 3 mg/kg, fully inhibits platelet aggregation and also augments epicardial collateral flow during acute coronary occlusion.[5] However, the same dose of aspirin also abolishes completely the enhanced coronary flow response to 1.0 and 3.0 mg of intracoronary arachidonic acid,[20] presumably because it inhibits the arachidonic acid-induced synthesis of potent vasodilatory prostaglandins (prostacyclin, for example). It is therefore possible that the initial increases in collateral flow[3,5] and beneficial electrophysiologic effects[1,13] induced by aspirin during acute ischemia are eventually attenuated by inhibition of prostaglandin-mediated vasodilation, so that collateral flow and tissue perfusion are not maintained. Also, in the presence of profound ischemia, modest increases in collateral flow may not be sufficient to maintain myocardial viability. This explanation is compatible with the data of our previous study, in which we found that, although aspirin increased epicardial flow significantly (from 0.19 ± 0.04 to 0.34 ± 0.08 ml/min per g 4 hours after occlusion of the left anterior descending coronary artery), the final flow was only 30 percent of flow in normal nonischemic myocardium.[5]

Thus, despite aspirin's ability to inhibit platelet deposition and augment epicardial collateral flow in the dog, these potentially beneficial actions do not translate into salvage of ischemic myocardium and reduction in infarct size as assessed 72 hours after occlusion.

Regional Myocardial Kinetics of Lidocaine in Experimental Infarction: Modulation by Regional Blood Flow

RUBEN A. ZITO, MD, FACC
VINCENTE J. CARIDE, MD
THEODORE HOLFORD, PhD
BARRY L. ZARET, MD, FACC

The regional myocardial concentration of lidocaine after intravenous bolus administration was studied in the setting of myocardial infarction in 27 dogs utilizing a 24 hour old infarct model. Myocardial levels of lidocaine measured by gas chromatography were related to regional myocardial blood flow measured by radioactive microspheres in the same sample. A highly significant positive linear relation was noted between relative regional myocardial blood flow and lidocaine tissue concentration in animals killed 1 and 3 minutes after the injection of lidocaine ($R^2 = 0.81$ and 0.85, respectively). This positive linear relation was no longer evident at 5 or more minutes after injection of lidocaine. This lack of linear relation resulted from dramatic reductions in myocardial lidocaine concentration in normally perfused zones with much lesser reductions in lower flow zones. Thus the initial distribution of lidocaine after bolus injection is directly proportional to myocardial blood flow within the first 3 minutes of injection. Thereafter, the washout of lidocaine appears to be the dominant factor in myocardial distribution.

After acute myocardial infarction, drug delivery to the ischemic ventricular zone may be affected by the same pathophysiologic process—namely, a decrement in regional blood flow—that initially resulted in the infarct. Conventional monitoring of therapeutic efficacy based solely on plasma or serum drug levels would not provide insights into such a flow-related regional phenomenon and could lead to ineffective management. Such a situation would be particularly critical in relation to delivery of antiarrhythmic drugs. In this instance, failure to achieve an adequate drug concentration in a low flow arrhythmogenic zone of ventricular myocardium could result in lack of abolition of potentially lethal cardiac arrhythmias.[1,2]

This study examines, in the setting of experimental infarction, the effects of decreased regional myocardial blood flow on regional myocardial lidocaine kinetics at various times after intravenous bolus injection of the drug. Utilizing a 24 hour old canine myocardial infarct model, tissue lidocaine levels measured by gas chromatography were related to regional myocardial blood flow measured by the radioactive microsphere technique in the same samples.

Methods

Experimental preparation: A total of 27 mongrel dogs of either sex weighing between 20 to 30 kg were studied. Following anesthesia with intravenous sodium pentobarbital (30 mg/kg), acute anterior wall myocardial infarction was induced by a closed chest catheter plug embolization technique described previously.[3] Briefly, a 7 Sones catheter was advanced through the right carotid artery into the aortic root and positioned subselectively under fluoroscopic control in the orifice of the left anterior descending coronary artery. A radiopaque plug made of catheter material and impaled on the distal end of a guide wire previously placed within the catheter was then dislodged into the coronary artery. This was

achieved by pulling back on the proximal end of the guide wire. The plug usually occluded the distal third of the coronary artery at the point of origin of the last large diagonal branch from the anterior descending artery.

Lidocaine groups: After infarction, the dogs were allowed to recover for 24 hours. The animals with 24 hour old infarcts were then reanesthetized and a lateral thoracotomy was performed. A cannula was placed in the left atrial appendage for the injection of radioactive microspheres necessary for measurement of relative regional myocardial blood flow.[5,6] Each dog then received lidocaine, 1.5 mg/kg, as an intravenous injection over 1 minute through a peripheral vein. The dogs were separated into six groups of four to five animals. The groups were defined by the time after completion of the lidocaine injection at which the dogs were killed. These times were 1, 3, 5, 15, 30 and 120 minutes after the administration of the total lidocaine dose. Before termination of each experiment, 1.1 to 2.2 × 10^6 radiolabeled microspheres (strontium-85) 15 ±5μ in diameter (3M Corporation) were injected by way of the left atrial cannula. The dogs were killed and the hearts rapidly removed. Blood samples from a different peripheral vein were also obtained immediately before the dogs were killed.

Myocardial tissue samples: Approximately 12 full thickness myocardial samples were obtained from the infarcted portion of the left ventricle. Six to eight additional normal left ventricular tissue samples were obtained from the normal ventricular region supplied by the circumflex coronary artery remote from the infarcted area. Tissue samples were blotted to remove blood from the tissue. Samples from the normal zone were obtained immediately after removal of the heart as well as at the end of the tissue-harvesting procedure (10 dogs, studied at 1 and 3 minutes). Comparison of lidocaine data in these normal tissues allowed assessment of any possible postmortem leakage of the drug from myocardial tissue during the period of tissue dissection before the sample was obtained and placed in a test tube. All myocardial samples were divided in half, representing endocardial and epicardial portions and were weighed. Sample weight ranged from 0.4 to 3.5 g. Samples were then placed in scintillation vials containing 4 cc of 10 N sodium hydroxide per gram of tissue (for subsequent homogenization) and the radioactivity was measured in an automated gamma counter (Beckman 8000 gamma counter, Irvine, California). After gamma counting for microsphere activity the tissue was homogenized using an ultrasonic cell disrupter (model WD-225-R Heat Systems-Ultrasonic Inc., Plainview, New York) and the sample frozen until analyzed subsequently with gas chromatography. Blood samples were centrifuged, and the plasma saved was frozen for lidocaine determination.

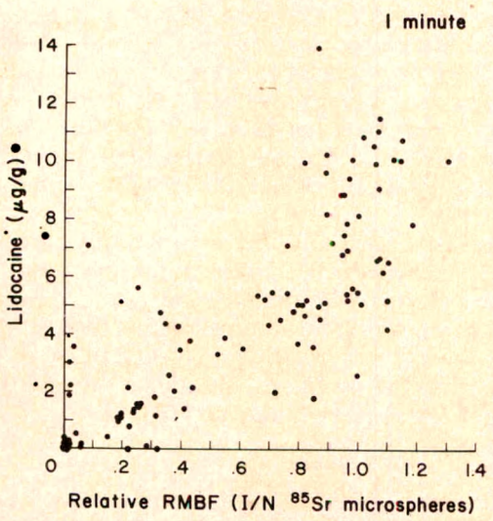

FIGURE 1. Relation between regional myocardial concentration of lidocaine (micrograms per gram of tissue) and relative regional myocardial blood flow (RMBF) expressed as a ratio of radioactivity in the infarct (I) zone compared with the mean value of all normal (N) myocardial samples in each animal 1 minute after intravenous lidocaine injection. Statistical analyses of the data are found in the text. ^{85}Sr = strontium-85.

Lidocaine assay: Lidocaine in blood and tissues was measured with the technique of Benowitz and Rowland.[7] Homogenized tissue samples were processed in the same manner as the plasma samples. The technique consists of the following steps: Plasma or tissue homogenate, 1 to 2 ml, was placed in a screw-capped centrifuge tube; then 0.5 ml of 2-diethylaminoacetanilide (Kodak) was added. After the addition of 7 ml of distilled ether, the solution was shaken for 1 minute and centrifuged (room temperature) at 3,000 rpm. The ether layer was transferred to a conical tube containing 0.2 ml of 0.1N hydrochloric acid. After manual shaking for 1 minute, the mixture was centrifuged at 3,000 rpm for 10 minutes and the ether layer discarded. Then 0.1 ml of 0.5N sodium hydroxide was added for alkalinizing the solution and 50 μ-liters of carbon disulfide was also added. After vortexing and centrifuging, the lower carbon disulfate phase was carefully sampled with a Hamilton syringe and 2 μliters injected into the gas chromatograph (GC 6AM Shimadzu, Columbia, Maryland). The ratio of lidocaine to the internal standard was calculated by comparison of the area under the curve of the respective peaks and the concentration was determined with reference to the standard curve. Standard curves were prepared every day from plasma or tissue, or both, thus allowing for compensation for any incomplete recovery from samples from cardiac tissue or plasma. Linear standard curves were obtained with similar ratios for water, plasma and cardiac tissue. The lower limit of sensitivity of the assay is 0.01 μg/ml, well below the concentrations obtained in this study. Homogenized cardiac tissue and plasma from control animals not receiving lidocaine showed no peak that might interfere with measurement of lidocaine or the internal standard. The coefficient of variability for the same samples was approximately 10 percent.

Statistical analysis: Data from these studies are expressed as absolute concentrations of lidocaine in micrograms/gram of myocardial tissue or micrograms/milliliter of serum. The infarct to normal ratio for the microspheres represents a relative measure of regional myocardial blood flow and is a ratio of activity in the infarct zone sample as compared with the mean value of all normal samples in that animal.

Data are expressed as mean ± standard error of the mean. The analysis of variance and multiple regression was carried out using PROG GLM in the SAS satistical package.[8] Differences between groups were determined with Student's *t* test; a value of $p < 0.05$ was considered significant.

Results

Relation between regional myocardial flow and lidocaine concentration (Fig. 1): A highly significant relation was noted between relative regional myocardial blood flow and lidocaine myocardial concentration in

animals killed 1 and 3 minutes after the lidocaine bolus injection. The relation was linear (R^2 0.83, 0.82, 0.59, 0.94 and 0.68, respectively, for the individual dogs killed at 1 minute and 0.48, 0.82, 0.85, 0.84 and 0.81, respectively, for those killed at 3 minutes. Pooling data of each time period into a single multiple regression, allowing for differences among dogs and between the epicardium and endocardium, gave a multiple correlation coefficient of $R^2 = 0.81$ at 1 minute and $R^2 = 0.85$ at 3 minutes. It should be noted that Figure 1 suggests a curvilinear relation between blood flow and lidocaine concentration. This was not apparent when the association was considered within dogs. The differences in trend among dogs are largely responsible for this phenomenon. Furthermore, at 1 and 3 minutes after injection of lidocaine, there were statistically significant decrements in myocardial lidocaine concentrations noted even at modest (60 to 80 percent of normal) blood flow reductions. These same significant decrements were also noted at lower blood flow ranges (Table I, Fig. 2) ($p < 0.01$) (Student's t test). Analysis of variance revealed that for both 1 and 3 minutes, relative blood flow was the single largest contributor to the sums of squares explained by the model, whereas for 2 hours the greatest source of variability was among dogs. At all three times there were significant differences in the effect of flow on lidocaine concentration among dogs. For 1 and 3 minutes the associations were all positive and highly significant but for 2 hours they were mixed, three dogs showing a fairly strong negative association and one a modest positive association with relative blood flow.

Normal flow zones versus low flow zones (Table I, Fig. 2): There was a rapid and dramatic reduction in myocardial lidocaine concentration with time noted in the normal flow zones. The reduction was substantially less in the lower flow zones, so that by 5 minutes after lidocaine injection there was no difference between concentrations of lidocaine in the lowest flow zone (less than 20 percent of normal) and in the normal zones. Thus, the initial distribution of lidocaine after bolus injection was directly proportional to regional blood flow. Shortly after distribution, the washout of lidocaine seemed to be the dominant factor in determining subsequent myocardial distribution.

Endocardial versus epicardial zones: There was a significant increase in endocardial lidocaine levels as compared with epicardial levels in normal flow zones at 1 minute, whereas the infarcted zones showed a trend to higher levels in the epicardium (p-not significant [NS]) (Table II). These findings were consistent with a greater decrement in flow in the endocardium than in the epicardium. As might be expected, on the basis of a flow-related deposition, this phenomenon was most apparent 1 minute after injection, and statistically significant trends were not apparent from 3 minutes after injection onward.

Infarcted versus normal myocardium: No simple relation existed between lidocaine myocardial and blood levels in various zones of infarcted and normal myocardium (Table III). The lidocaine myocardial blood ratio remained relatively constant in normal myocardium throughout the period of study, whereas it changed dramatically in zones of decreased flow, with a lower ratio during the initial 3 minutes after injection and a subsequent rise thereafter. These data indicate the difficulties of correlating lidocaine blood levels to local response in the first few minutes after bolus injection.

A comparison of lidocaine levels in normal myocardium harvested at the beginning and the end of tissue dissection period revealed comparable lidocaine levels (8.86 ± 0.44 μg/g [n = 29] versus 8.11 ± 0.41 μg/g [n = 28] [p-NS]; and 5.1 ± 0.32 μg/g [n = 31] versus 5.7 ± 0.6 μg/g [n = 23] [p = NS] at 1 and 3 minutes, respectively). Thus there was no efflux of lidocaine from the myocardial samples occurring during the time of tissue harvesting.

Discussion

Regional myocardial lidocaine pharmacokinetics: Our study indicates that after intravenous bolus injection, lidocaine distribution within the myocardium is dependent on regional myocardial blood flow. A spectrum of patterns of regional lidocaine pharmacokinetics can be distinguished, based on regional myocardial blood flow after infarction. At one extreme, in normally perfused myocardium, there is rapid equilibration with the blood. Lidocaine tissue levels in the normally perfused myocardium present the highest regional concentrations and peak early (at 1 minute after bolus administration. A rapid increase in lidocaine tissue levels is followed by a rapid reduction in lidocaine concentration. At the other end of the spectrum, lidocaine tissue levels in severely hypoperfused myocardium equilibrate more slowly, peak later than the well perfused compartment and have a delayed decline of lidocaine. Intermediate blood flow regions present intermediate patterns of lidocaine influx and efflux. These differences between compartments are most evident within the first 5 minutes after lidocaine bolus administration. After this distribution phase, lidocaine equilibrates in both compartments and declines in parallel with blood levels. Generally there are no differences in patterns of lidocaine kinetics between endocardium and epicardium that are independent of blood flow.

Effect of bolus injection versus constant infusion of lidocaine: Several aspects of this study are of interest. Our data were obtained entirely after bolus injection. Bolus injections are particularly useful to study the patterns of distribution of drugs in relation to time and blood flow. Blood flow is a major determinant of tissue distribution for many drugs. This was recently shown for lidocaine by Benowitz et al.[9] using a perfusion model. These relations between blood flow and drug distribution are of obvious importance in myocardial infarction. The studies of these relations cannot be obtained using constant infusions, although this is the most common way of administering lidocaine to patients.

Data from bolus injection are in contrast to recent observations[10] from our laboratory involving lidocaine

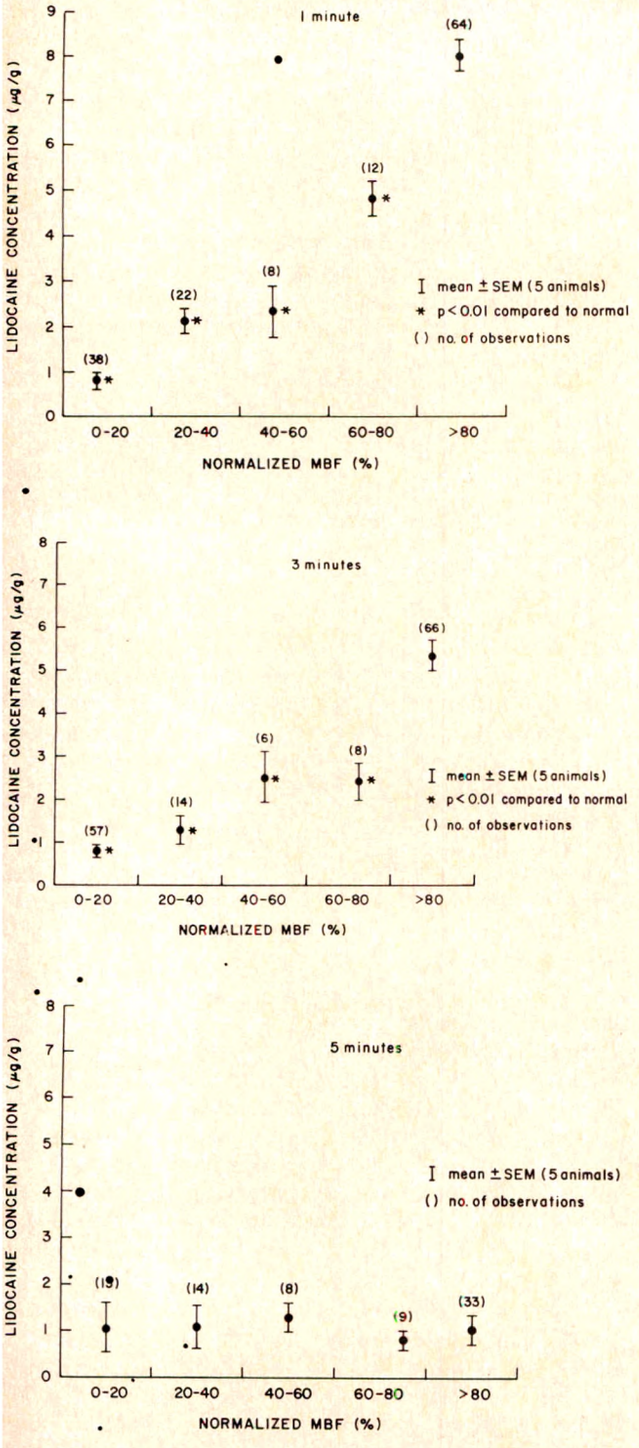

FIGURE 2. Regional myocardial concentration of lidocaine (micrograms per gram of tissue ± standard error of the mean [SEM]) expressed as a function of regional myocardial blood flow (MBF), as measured by the radioactive microsphere technique. Data for 1 minute and 3 and 5 minutes are presented in the **top, middle** and **bottom** panels, respectively. The data are clustered into five groups depending on relative regional myocardial blood flow in the tissue sample. The number of samples corresponding to each flow zone is given in parentheses. Statistical analysis was made by comparing lidocaine concentration in each flow group with the control lidocaine concentration in areas with greater than 80 percent regional myocardial blood flow. Note that lidocaine in the ischemic section differed significantly at 1 and 3 minutes but not at 5 minutes.

constant infusion in which low blood flow zones in ischemic myocardium reached concentrations of lidocaine approximately 40 percent of the levels reached in normal myocardium. After lidocaine infusion of 35 μg/kg per min, a tissue concentration of 3.5 μg/g of lidocaine was found in the normal tissue and of 1.2 μg/g in the most hypoperfused tissues with flows lower than 0.2 ml/min per g. In contrast, with bolus injection lidocaine concentration in low blood flow zones was only 10 percent of that in the normal zones at the peak of blood level at 1 minute. This relatively higher concentration of lidocaine in low blood flow zones during constant infusions probably represents the differences in kinetics between the bolus and constant infusions.

Similar observations were made by Wenger et al.[11] *using a constant infusion of procainamide.* They studied the relation of procainamide and myocardial blood flow during acute ischemia in a canine model. Procainamide was administered as a continuous infusion over 4 hours to what was presumed to be a steady state and the drug tissue levels were measured using a radiochemical combustion technique in which procainamide concentrations were determined from activity collected in the form of carbon-14 carbon dioxide. Myocardial levels of procainamide were maximal in regions with more than 40 percent of normal regional myocardial blood flow. Below this blood flow level, there was a persistent decrement in procainamide levels. However, even in zones with less than 10 percent of normal blood flow, procainamide concentrations were 40 percent of normal as in our results. The reasons for this concentration against flow in the infarcted myocardium as well as the equilibration of lidocaine tissue levels after 30 minutes seen in our study are unclear. However, we can speculate that the mechanisms for lidocaine accumulation in ischemic myocardium may be related to the local properties of the ischemic myocardium. Increased residence time, binding of the drug to molecules such as phospholipids from cell membranes that have been disrupted as a result of ischemia and necrosis, altered metabolism of the drug in the infarcted area and markedly delayed efflux out of the infarcted area may be responsible for this phenomenon.

Methodologic considerations: Several aspects of the model used in our study deserve comment. A 24 hour infarct model was employed. At this particular time, myocardial blood flow is relatively stable and one would not expect intra-study differences in regional flow based on changing patterns of collateral blood flow.[12] From a methodologic standpoint, measurements of flow and measurements of tissue drug level were obtained using two different techniques applied to the same sample. The blood flow measurement was made with radioactive microspheres, whereas the drug myocardial level was assessed with gas chromatography. Therefore, a single sample did not have to be subdivided before analysis to obtain portions of tissue for independent measurement of flow and drug levels. Although attempts were made to remove blood from the myocardial samples by tissue blotting, it is probable that not all

* Values are mean ± standard error of the mean (SEM) of ratios of μg/g of lidocaine in tissue to μg/ml of lidocaine in serum. † Refers to time dogs were killed after intravenous bolus infusion of lidocaine; ‡ Relative regional myocardial blood flow as assessed with strontium-85 microspheres (1.0 = 100 percent control activity).

blood was removed. Therefore, the myocardial lidocaine level may, in a small part, be a function of residual blood activity as well as of tissue drug concentrations. Nevertheless, these data do represent delivery of drug to a given myocardial region.

Relation between tissue levels of lidocaine in ischemic tissue and antiarrhythmic efficacy: This relation is uncertain. Kupersmith et al.[13] pointed out the importance of studying the delivery of lidocaine to understand lidocaine's antiarrhythmic effect. These investigators explained some of lidocaine's electrophysiologic effects in ischemic myocardium by the time course of drug delivery to deep ischemic layers of myocardium. Our finding that lidocaine may exhibit significant delay in reaching deep layers of myocardium are in agreement with this explanation. However, this may vary depending on the model utilized and the time of the study after infarction.

The demonstration of altered tissue distribution of an antiarrhythmic drug represents a first step toward a more detailed study of the interactions of regional pharmacokinetics and pathophysiology. Drug tissue levels must be related to regional electrophysiologic variables to assess the therapeutic efficacy or lack thereof resulting from a flow-related distribution of the drug. Therapeutic effectiveness of an antiarrhythmic agent conceivably may occur even in the presence of an altered regional tissue distribution. Alternatively, the major focus of antiarrhythmic activity of the drug may reside in regions other than the ischemic myocardium, such as the central nervous system or the peripheral autonomic nervous system.

Clinical implications: Experimental electrophysiologic studies in dog models have suggested that arrhythmias may be generated in Purkinje tissues and nonhomogeneous infarcted or ischemic myocardium, or both.[1,2,14,15] These areas of myocardium are the likely sites of action of antiarrhythmic drugs. Giardina et al.[15] proposed that antiarrhythmic drugs such as procainamide may have their site of action in a slow equilibrating low blood flow compartment. Our results with lidocaine show that in poorly perfused myocardium there is a significant lag of time until maximal tissue concentration is reached and thereafter there also is a more gradual decrease. These observations also may support the hypothesis of Giardina et al. as applied to another antiarrhythmic agent.

Our data also are relevant to the clinical observation that lidocaine effect is delayed and lasts longer than expected when blood levels are analyzed following a bolus injection.[16] In addition, they also explain the early discrepancies in effective therapeutic blood levels found after bolus and constant infusions.[16] Although a constant infusion partially overcomes the effect of blood flow on regional lidocaine distribution, drug accumulation in low flow zones may be significantly delayed. Our study supports the recommendation by Bigger[17] of the use of an initial bolus injection of lidocaine together with the double infusion to avoid the initial delay seen with double infusion alone.

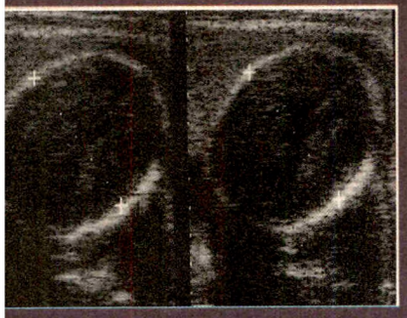
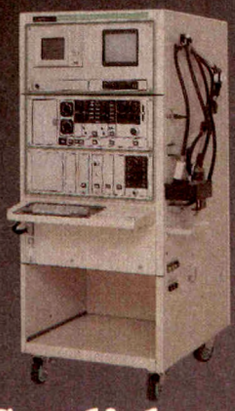
nly Toshiba's SSL-53M Ultrasound Uni
s built to work anywhere in the hospital

Ob/Gyn

oshiba's all new SSL-53M
asound instrument combines for
first time in one unit all the
tions necessary for cardiological
ies, general ob/gyn studies, and
ominal studies.
hat flexibility makes the SSL-53M
natural choice for hospitals seeking
to maximize their ultrasound
ars and diverse department
iencies.

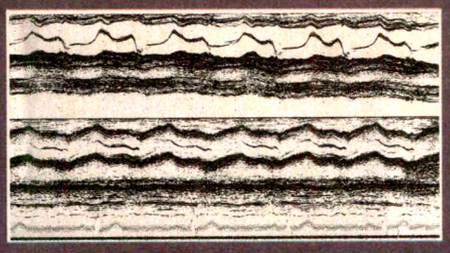


lectronic sector scanning, linear
ning and real time display of high
lution tomographic images allow
plete diagnostic visualization of
the abdomen and the dynamic
t.



Cardiology

Circulatory organ analyses are facilitated by such functions as 2-channel M mode, M mode scan, reference signal display with B mode



and single M mode probe. UCG, ECG and PCG along with apex wave and

Internal Medicin

carotid pulse, can be displayed simultaneously.

So if your concern is with radiolo cardiology, ob/gyn or general inter medicine, Toshiba's SSL-53M is th natural ultrasound choice.

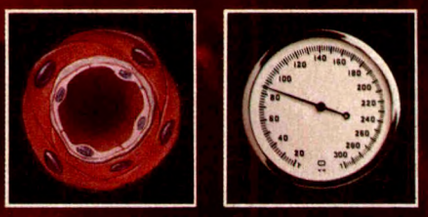
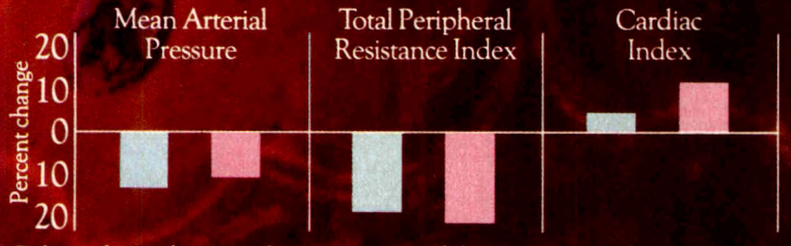
Controls Hypertension Peripheral Resistance



- MINIPRESS Reduces Mean Arterial Pressure
- MINIPRESS Reduces Total Peripheral Resistance
- MINIPRESS Does Not Reduce Cardiac Index

...and Maintains These Effects Over the Long Term



Relative hemodynamic changes at rest and during exercise after one year of prazosin therapy in 10 hypertensive patients. Adapted from Lund-Johansen[1]

Rest Exercise

MINIPRESS®

(prazosin HCl)

Capsules 1 mg, 2 mg, 5 mg

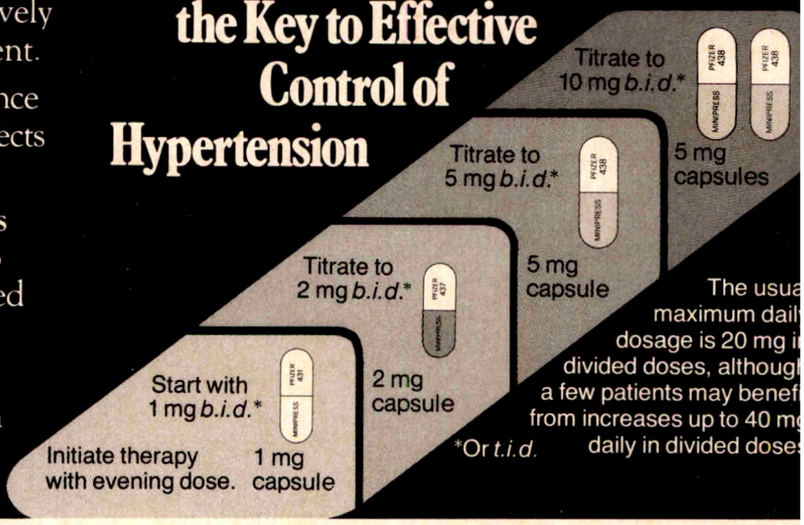
Please see Brief Summary on last page.

© 1980, Pfizer Inc.

MINIPRESS
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

- **Effectively lowers elevated blood pressure by reducing peripheral resistance.**
- **Maintains cardiac output** which allows patients to maintain an active life style.
- **Maintains renal blood flow and glomerular filtration rate** so it can be used effectively even in patients with renal impairment.
- **Not a CNS agent** so patients experience few of the troublesome CNS side effects that impair their quality of life.
- **Cardiovascular response to exercise is preserved** so patients are less likely to experience the fatigue often associated with beta-blocker therapy.
- **A small percentage of patients** have experienced orthostatic hypotension and syncope.

B.I.D. Dosage Titration... the Key to Effective Control of Hypertension



BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*

INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.

WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established).

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus.

Genitourinary: urinary frequency, incontinence, impotence.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings).

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy, however a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

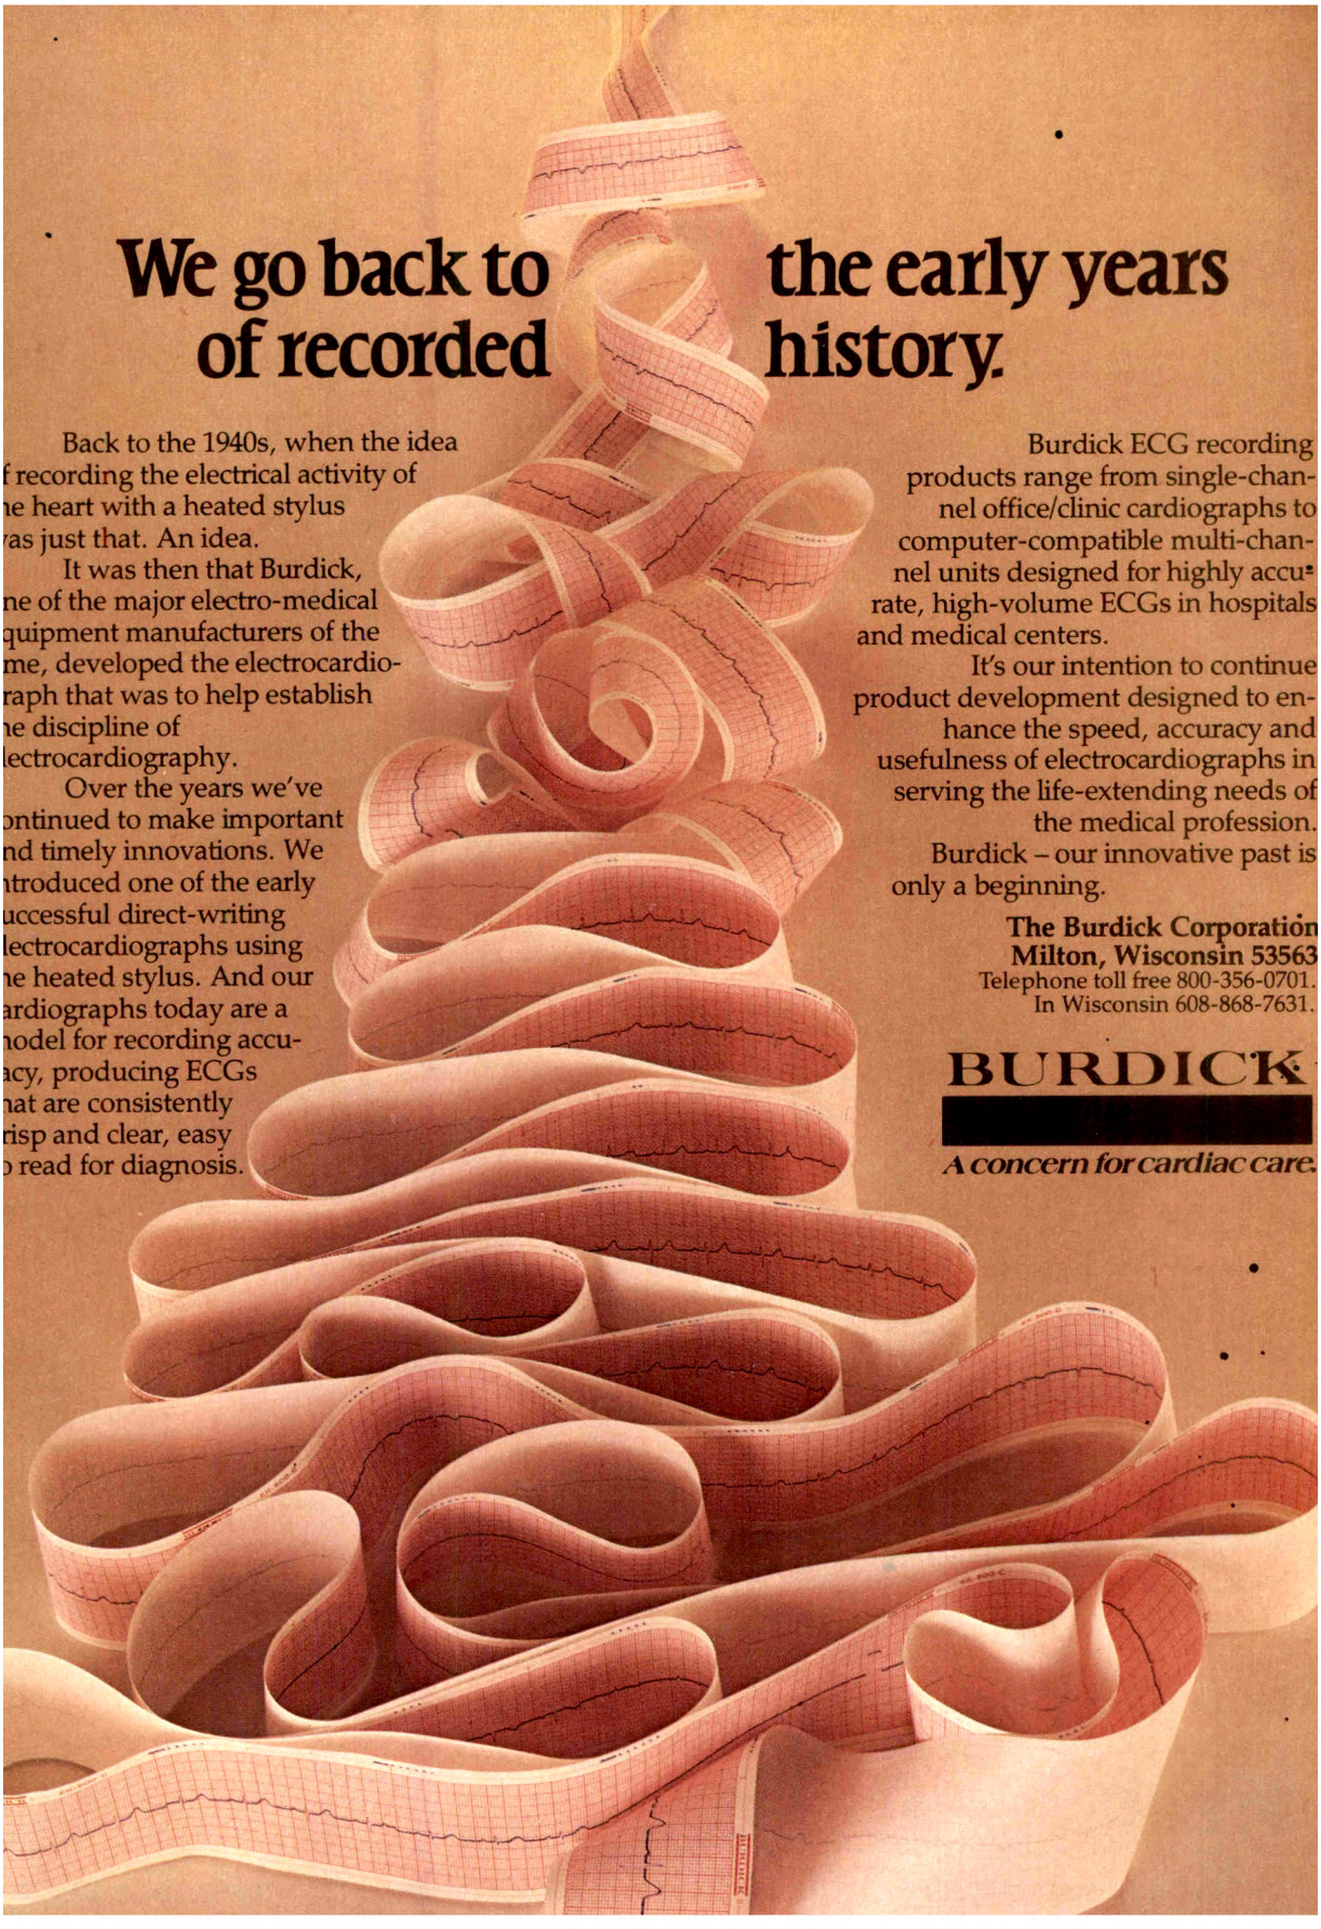
Pfizer **LABORATORIES DIVISION**
PFIZER INC.



We go back to the early years of recorded history.

Back to the 1940s, when the idea f recording the electrical activity of ıe heart with a heated stylus ⁄as just that. An idea.

It was then that Burdick, ne of the major electro-medical quipment manufacturers of the me, developed the electrocardio-raph that was to help establish ıe discipline of lectrocardiography.

Over the years we've ontinued to make important nd timely innovations. We ıtroduced one of the early uccessful direct-writing lectrocardiographs using ıe heated stylus. And our ardiographs today are a ıodel for recording accu-acy, producing ECGs ıat are consistently risp and clear, easy ɔ read for diagnosis.

Burdick ECG recording products range from single-channel office/clinic cardiographs to computer-compatible multi-channel units designed for highly accurate, high-volume ECGs in hospitals and medical centers.

It's our intention to continue product development designed to enhance the speed, accuracy and usefulness of electrocardiographs in serving the life-extending needs of the medical profession.

Burdick – our innovative past is only a beginning.

SIEMENS-ELEMA

Shown actual size:
53X48.5X13.2 mm.
Volume: 26 cm³.
Weight: 48 g.

- **Comprehensive programmability for optimum performance.**
- **Easy threshold follow-up with the unique Vario® system.**
- **High output—10V.**
- **Distinct and double ERT-criteria for maximum patient safety.**

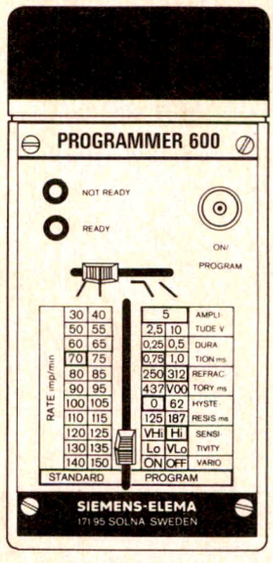
THE MULTIPROGRAMMABLE PULSE GENERATOR 668. FROM SIEMENS-ELEMA—THE PEOPLE WHO PIONEERED THE FIRST IMPLANTABLE PACEMAKER IN 1958.

Specifications 668

FUNCTION		Inhibited (VVI or AAI) or fixed rate (VOO or AOO)
PULSE DURATION		0.25, 0.5, 0.75, or 1.0 ms
PULSE AMPLITUDE		2.5, 5, or 10 V (new unit)
PULSE RATE		22 different rates; from 30 to 150 imp/min
RUN-AWAY PROTECTION		Max. 180 imp/min in case of electronic malfunction
TEST RATE		100 imp/min for new generator (test magnet applied)
REFRACTORY PERIOD		250, 312, 437 ms or ∞ (fixed rate)
HYSTERESIS		0, 62, 125, or 187 ms
R-WAVE SENSITIVITY		0.7, 1.1, 1.4 and 2.0 mV
POWER SOURCE		One lithium-iodine cell CRC 810C/23 or equivalent
CURRENT DRAIN		Depends on parameter settings. At standard program: 100% stim. approx. 20 μA; Inhibited approx. 5 μA
BATTERY DEPLETION INDICATIONS	TEST RATE	85 imp/min
	BASIC RATE	20% drop from programmed value. Occurs a few months after the test rate of 85 imp/min has been passed
	PULSE DURATION	Increases to 1.5 ms when basic rate drops by 20%
WEIGHT		48 g
LEAD CONNECTION		Unipolar plug-in socket, diameter 6 mm

For more detailed specifications, see separate product catalog or operating instructions.
Specifications subject to alteration without prior notice.

The PROGRAMMER 600 is a pocket-size, easy-to-handle programming unit.



Programming unit for 668 generator features simple and straightforward operation, can also be used as pulse generator test magnet.

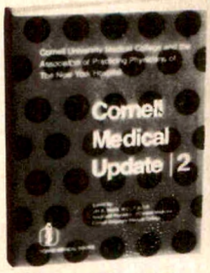
Update Your Medicine lectures.

CORNELL MEDICAL UPDATE/2



Edited by LILA A. WALLIS, MD, FACP

Helps you keep up with the new advances in your specialty in the comfort of your home or office.

All new material—specialties expanded.

The workbook format of the CORNELL MEDICAL UPDATE/2 breaks medical publishing traditions by giving practicing physicians a quick overview of the latest advances in their specialty. It transcribes the Update Your Medicine lectures sponsored by New York Hospital-Cornell Medical Center. These lectures are well-known for helping physicians prepare for Recertification despite the demands of a heavy practice

The new approach of the first volume was so well-received that it went through three printings in less than two years. Now the just published CORNELL MEDICAL UPDATE/2 takes up where the first volume left off. It has been specially designed for the practicing physician who has difficulty keeping up with the growing literature of the field. Each chapter transcribes one of the lectures and covers a specific speciality in-depth from basic physiologic and chemical principles to its clinical applications.

Lila A. Wallis, MD, FACP, the series editor, has eliminated all the filler material a *continuing* education does not need. You won't find historical reviews or a rehash of material you've known since medical school. You will find the practical, life-saving knowledge a dynamic practice depends on. Because the lectures have been edited for easy reading and laid out for quick comprehension, you'll be able to incorporate all the material into your own professional technique.

Earn 25 Credits Towards AMA Physician's Recognition Award. CORNELL MEDICAL UPDATE/2 has been approved for Category 1 credit towards the AMA's Physician's Recognition Award for Continuing Medical Education. Full details on how to apply for credit are included with every copy.

Yorke Medical Books, 666 5th Ave., N.Y., N.Y. 10103 AJC 2/81

Please send me a copy of CORNELL MEDICAL UPDATE/2 at $38.00. I may use the book for 30 days and if not completely satisfied, return it for full refund or credit.

amily of Man" by Roberto Moretti,
uary in crystal symbolizing the broad range of
tensive patients eligible for therapy with Catapres.

The Alpha Advantage:

It's for all kinds of hypertensives

- *Unlike beta blockers, Catapres® has no contraindications.*
- *Catapres can be useful even in these patients with:*

Congestive heart failure	Allergic rhinitis
Ventricular hypertrophy	Hepatic disease
Hyperglycemia	Hyperuricemia
Diabetes mellitus	Gouty arthritis
Bronchial asthma	Sulfonamide hypersensitivity

Like any antihypertensive, use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

work/play—normal hemodynamic responses to exercise maintained.

love—low incidence of impotence and/or loss of libido: 2.8% in 1,923 patients studied.[1]

cardiac output—tends to return to control values during long-term therapy.

blood flow—preserved in kidney.

No Single Advantage Determines Drug Choice.

Other factors must include:

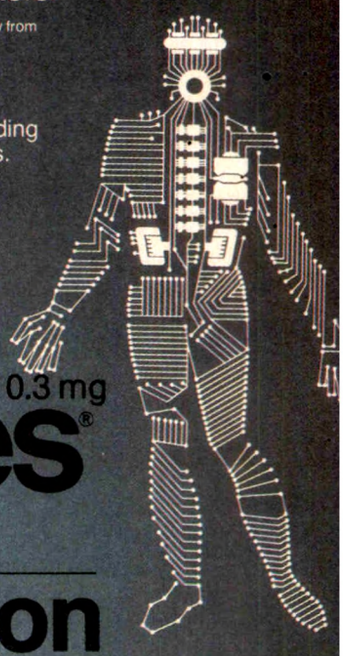
The drug's effectiveness in a given patient, its side effects, warnings, precautions, tolerance, etc. A rational therapeutic choice depends on a careful assessment of all such factors.

*Central alpha-adrenergic stimulation decreases sympathetic outflow from the brain, as shown in animal studies.

1. Data on file at Boehringer Ingelheim Ltd.

Please see last page for brief summary, including warnings, precautions, and adverse reactions.

Now available in new 0.3 mg tablets

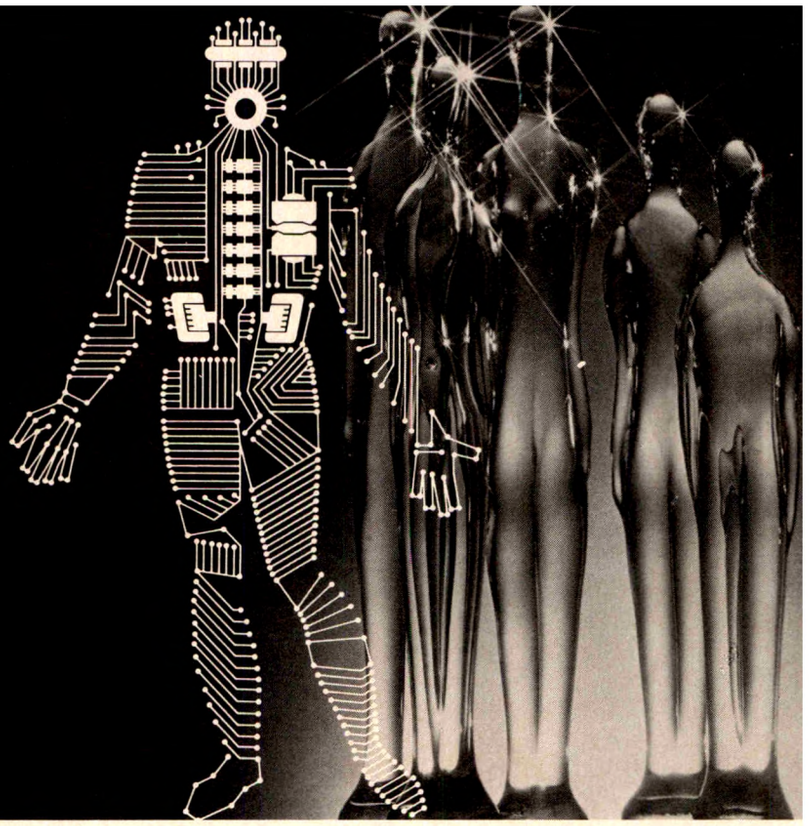


Tablets of 0.1, 0.2, 0.3 mg

Catapres®
(clonidine HCl)
Hypertension

The Alpha Advantage:

It's for all kinds of hypertensives



Tablets of 0.1, 0.2, 0.3 mg

Catapres®

(clonidine HCl)

Hypertension

- No contraindications.
- Effective in all degrees of hypertension. It is mild to moderate in potency.
- Low incidence of depression, impotence, orthostatic hypotension—no fatal hepatotoxicity.
- Preserves kidney blood flow.

Most common side effects are dry mouth, drowsiness, and sedation which generally tend to diminish with time.

The usual starting dose of Catapres is 0.1 mg at breal fast and 0.1 mg at bedtime. Some patients may benef from a starting dose of 0.1 mg at bedtime.

Usual daily dose range—0.2—0.8 mg

Maximum daily dose—2.4 mg
Doses as high as this have rarely been employed.

For optimal results, the dose of Catapres must be adjusted according to the patient's individual blood pressure response.

Catapres®
(clonidine hydrochloride)
Tablets of 0.1, 0.2, 0.3 mg

Indication: The drug is indicated in the treatment of hypertension. As an antihypertensive drug, Catapres (clonidine hydrochloride) is mild to moderate in potency. It may be employed in a general treatment program with a diuretic and/or other antihypertensive agents as needed for proper patient response.

Warnings: Tolerance may develop in some patients necessitating a reevaluation of therapy.
Usage in Pregnancy: In view of embryotoxic findings in animals, and since information on possible adverse effects in pregnant women is limited to uncontrolled clinical data, the drug is not recommended in women who are or may become pregnant unless the potential benefits outweigh the potential risk to mother and fetus.
Usage in Children: No clinical experience is available with the use of Catapres (clonidine hydrochloride) in children.

Precautions: When discontinuing Catapres (clonidine hydrochloride), reduce the dose gradually over 2 to 4 days to avoid a possible rapid rise in blood pressure and associated subjective symptoms such as nervousness, agitation, and headache. Patients should be instructed not to discontinue therapy without consulting their physician. Rare instances of hypertensive encephalopathy and death have been recorded after cessation of clonidine hydrochloride therapy. A causal relationship has not been established in these cases. It has been demonstrated that an excessive rise in blood pressure, should it occur, can be reversed by resumption of clonidine hydrochloride therapy or by intravenous phentolamine. Patients who engage in potentially hazardous activities, such as operating machinery or driving, should be advised of the sedative effect. This drug may enhance the CNS-depressive effects of alcohol, barbiturates and other sedatives. Like any other agent lowering blood pressure, clonidine hydrochloride should be used with caution in patients with severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease or chronic renal failure.

As an integral part of their overall long-term care, patients treated with Catapres (clonidine hydrochloride) should receive periodic eye examinations. While, except for some dryness of the eyes, no drug-related abnormal ophthalmologic findings have been recorded with Catapres (clonidine hydrochloride), in several studies the drug produced a dose-dependent increase in the incidence and severity of spontaneously occurring retinal degeneration in albino rats treated for 6 mont longer.

Adverse Reactions: The most common reactions are dry mouth, drowsines sedation. Constipation, dizziness, headache, and fatigue have been repo Generally these effects tend to diminish with continued therapy. The follo reactions have been associated with the drug, some of them rarely. (In s instances an exact causal relationship has not been established.) These inc Anorexia, malaise, nausea, vomiting, parotid pain, mild transient abnormalit liver function tests; one report of possible drug-induced hepatitis without ic and hyperbilirubinemia in a patient receiving clonidine hydrochloride, c thalidone and papaverine hydrochloride. Weight gain, transient elevation of l glucose, or serum creatine phosphokinase: congestive heart failure, Rayn phenomenon; vivid dreams or nightmares, insomnia, other behavioral cha nervousness, restlessness, anxiety and mental depression. Also rash gioneurotic edema, hives, urticaria, thinning of the hair, pruritus not assoc with a rash, impotence, urinary retention, increased sensitivity to alcohol, dry itching or burning of the eyes, dryness of the nasal mucosa, pallor, gynecom weakly positive Coombs' test, asymptomatic electrocardiographic abnorma manifested as Wenckebach period or ventricular trigeminy.

Overdosage: Profound hypotension, weakness, somnolence, diminished c sent reflexes and vomiting followed the accidental ingestion of Catapres (clon hydrochloride) by several children from 19 months to 5 years of age. G lavage and administration of an analeptic and vasopressor led to complet covery within 24 hours. Tolazoline in intravenous doses of 10 mg at 30-m intervals usually abolishes all effects of Catapres, (clonidine hydrochloride) dosage.

How Supplied: Catapres, brand of clonidine hydrochloride, is available as 0. (tan) and 0.2 mg (orange) oval, single-scored tablets in bottles of 100 and 1000. available as 0.3 mg (peach) oval, single-scored tablets in bottles of 100.

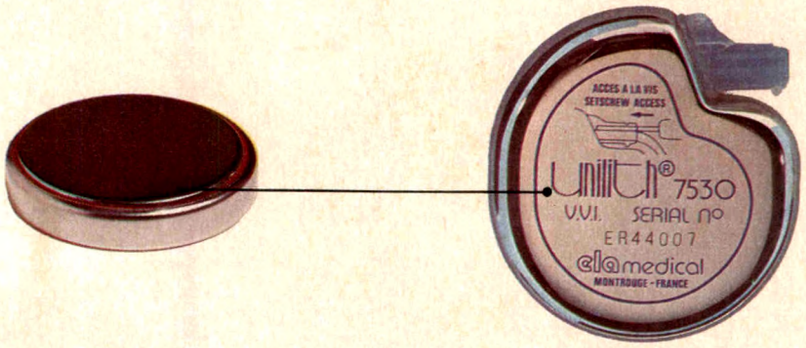
AT LAST

A guaranteed pacemaker battery



The SAFT cell Li 355/6, chosen by ELA MEDICAL
for its Unilith® models 7530 and 7730,
represents the culmination of many years of clinical experience combined with thorough laboratory testing.
This cell, connected to ELA MEDICAL'S Unilith® circuits 7530 (0.5 ms) and 7730 (0.7 ms), is guaranteed for four years from date of implantation, irrespective of load.
This major "First" in the field of cardiac pacing is a direct result of close cooperation betwe ELA MEDICAL, who has tested these cells extensively and SAFT who has confirmed them to be perfectly compatible with the circuitry.

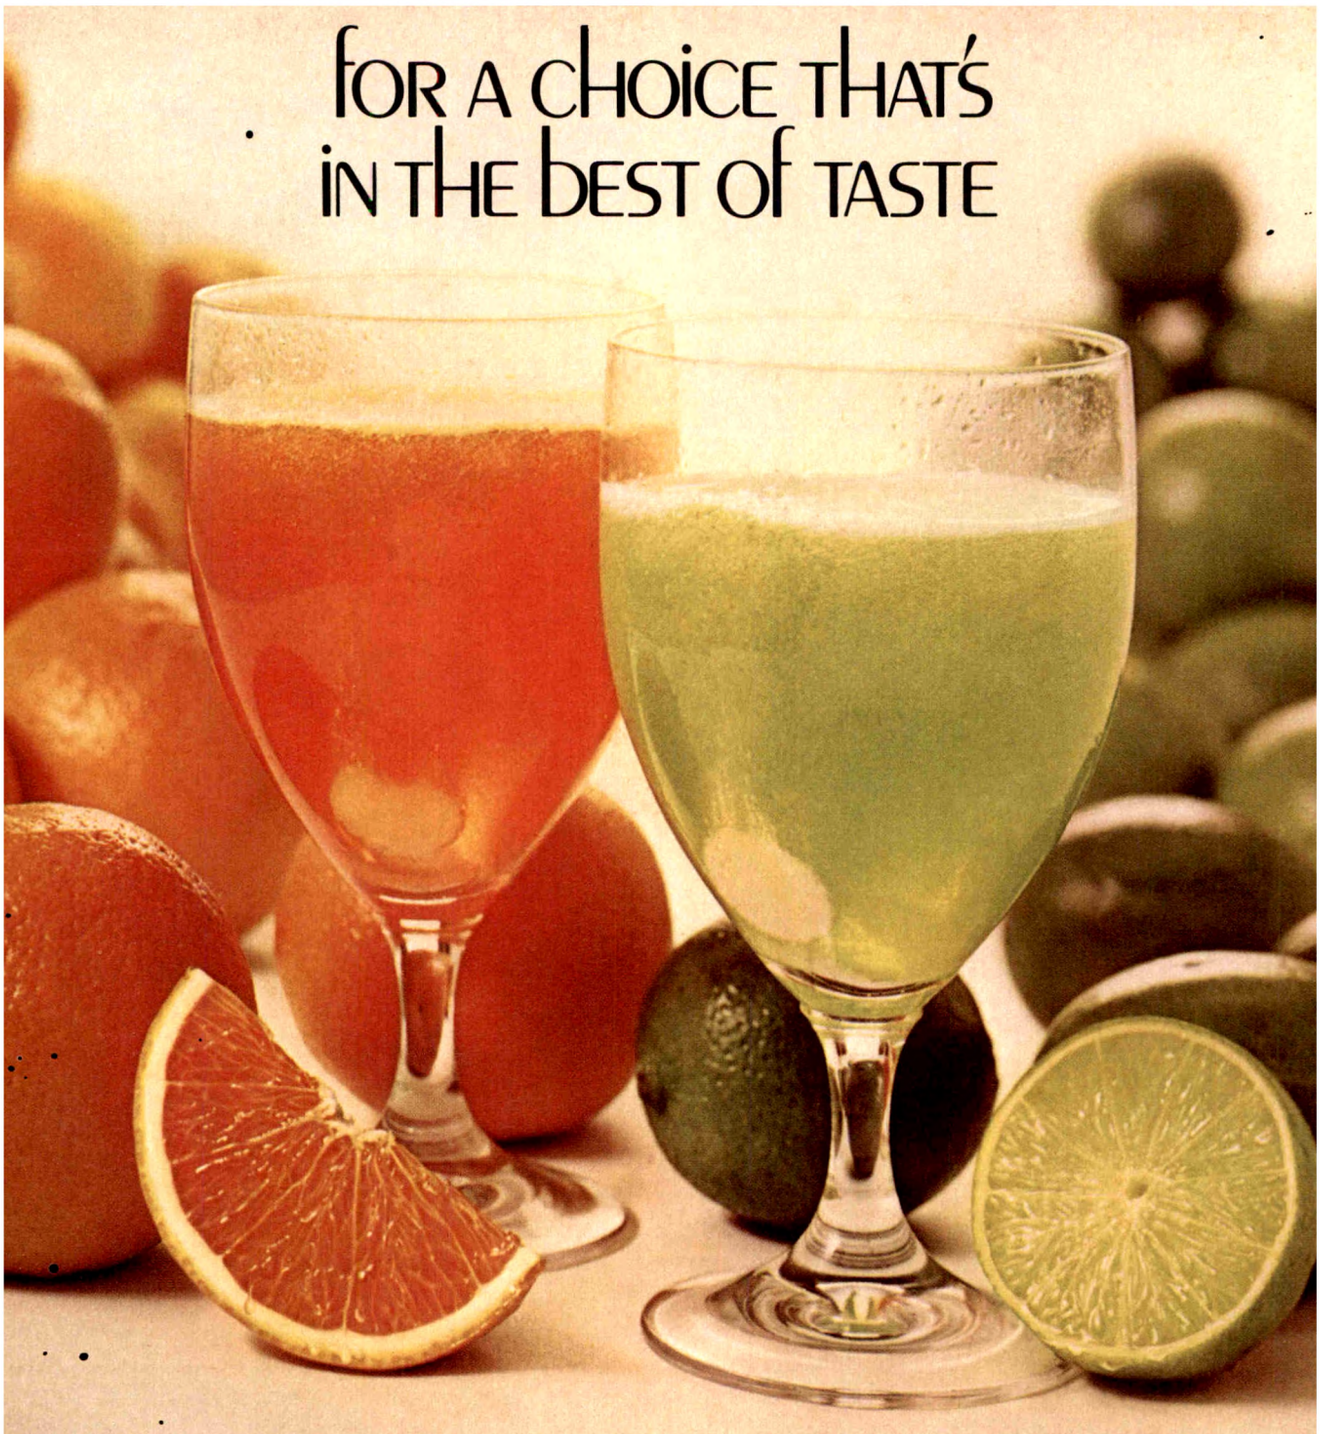
FOR A CHOICE THAT'S IN THE BEST OF TASTE



K-LYTE®

Each effervescent tablet in solution supplies 25 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
The best of taste for over a decade

K-LYTE® DS

Each effervescent tablet in solution supplies 50 mEq potassium as bicarbonate and citrate

Orange and Lime Flavors
Convenient once-a-day dosage

Prescribing Considerations

Indications: K-LYTE DS and K-LYTE are oral potassium supplements for therapy or prophylaxis of potassium deficiency. They are particularly useful when thiazide diuretics, corticosteroids, or severe vomiting and diarrhea cause excessive excretory potassium losses; and when dietary potassium is low. Carefully monitored, K-LYTE DS and K-LYTE may also be useful for potassium replacement where digitalis intoxication results in cardiac arrhythmias.

Contraindications: Impaired renal function with oliguria or azotemia; Addison's disease; hyperkalemia from any cause.

Warnings and Precautions: Since the amount of potassium deficiency may be difficult to determine accurately, supplements should be administered with caution, and dosages adjusted to the requirements of the individual patient. Potassium intoxication rarely occurs in patients with normal kidney function. Symptoms of potassium intoxication are variable. They include listlessness, mental confusion, and tingling of the extremities. Frequent checks of the clinical status of the patient, ECG, and serum potassium level are desirable. In established hypokalemia, attention should also be directed toward other potential electrolyte disturbances. Potassium supplements should be given cautiously to digitalized patients and such patients should be monitored by ECG for cardiac irregularities. To minimize the possibility of gastrointestinal irritation associated with the oral ingestion of concentrated potassium salt preparations, **patients should be carefully directed to dissolve each dose completely in the stated amount of water.**

Adverse Reactions: Nausea, vomiting, diarrhea, and abdominal discomfort may occur with the use of potassium salts.

Dosage and Administration: Adults: 1 K-LYTE DS tablet (50 mEq potassium) completely dissolved in 6 to 8 ounces of cold or ice water, 1 to 2 times daily; 1 K-LYTE tablet (25 mEq potassium) completely dissolved in 3 to 4 ounces of cold or ice water, 2 to 4 times daily. **NOTE: It is suggested that K-LYTE DS and K-LYTE be taken with meals and sipped slowly over a 5 to 10 minute period.**

How Supplied: K-LYTE DS effervescent tablets (orange or lime flavors) are available in cartons of 30 and 100. K-LYTE effervescent tablets (orange or lime flavors) are available in cartons of 30 and 250. All tablets are individually foil wrapped.

Marquette Breaks The Cost Barrier In Computer ECG Processing

Marquette Electronics has developed a new low cost ECG Processing System for small and medium sized hospitals. The **MUSE D-96**, selling for $71,000 complete with software, will be introduced at the American College of Cardiology Meeting, March 16 - 19, 1981 in San Francisco.

Central ECG analysis and processing systems using digital computers have been available for almost ten years. They can analyze ECGs, store tracings and reports on magnetic discs, produce final reports, and prepare statistical studies. One central processor can serve many remote health care facilities or can be shared by several hospitals. But the cost is high, generally over the $100,000 ceiling set in most states by the HSA, thereby requiring a Certificate of Need. Only the largest hospitals can justify such equipment unless several hospitals can get together and share a single system.

The New Marquette **MUSE D-96** system can provide the important functions of the larger systems; including acquiring ECG by telephone or tape, analyzing with Marquette's new 12 Simultaneous Lead Analysis Program, storing of 30,000 ECGs, editing, and producing final reports. In most states a Certificate of Need will not be required for the **MUSE D-96**, and hospitals as small as 200 beds can justify owning a system of their own.

The **MUSE D-96** will be demonstrated in major cities following the A.C.C. Meeting in March. Use the attached postcard or call our toll free number (1-800-528-6050, extension 1505) for additional information and the date of a demonstration convenient for you. In Arizona call (1-800-352-0458, extension 1505).

Another Step Forward In Electrocardiography... 12 Simultaneous Leads

Marquette Electronics' philosophy is, and always has been, to make basic contributions in the field of electrocardiography.

Thus when we decided to write our new ECG computer analysis program two years ago, we were determined to find a way to make this program not just better, but much better.

Of course, when we introduced three channel telephone transmission in 1966, computer programs improved considerably by virtue of the ability to analyze three leads at the same time.

Then in 1978, we developed a method to acquire and transmit to a computer all twelve leads digitally and **simultaneously**, without adding noise or distortion of any kind.

This development made it possible to derive much more accurate and reliable measurements of the ECG waveforms. And, with these measurements the computer program can provide analyses with greatly improved sensitivity and specificity.

We have now installed several ECG Processing Systems using the new Marquette Analysis Program. Initial reports indicate the program is producing an interpretation with a much higher level of physician agreement.

Use the attached postcard or call our toll free number (1-800-528-6050, extension 1505) for additional information. In Arizona, call (1-800-352-0458, extension 1505).

Noninvasive Methods for Detection of Valve Vegetations in Infective Endocarditis

ELLEN T. MELVIN, MD*
MARVIN BERGER, MD, FACC
LETTY G. LUTZKER, MD
EMANUEL GOLDBERG, MD, FACC
DONNA MILDVAN, MD

New York, New York

To determine the optimal noninvasive method for the demonstration o endocarditic vegetations, 35 consecutive episodes of clinically diagnosec endocarditis in 33 patients were studied with M mode and two dimensiona echocardiography, and with gallium-67 citrate and technetium-99m stannous pyrophosphate cardiac scanning. Clinical criteria for the diag nosis of endocarditis were: temperature higher than 38° C; sustainec bacteremia with at least three positive blood cultures; no extracardiac focus of bacteremia; and known underlying heart disease, a new o changing murmur or a history of intravenous drug abuse with radiologic evidence of septic pulmonary emboli. M mode echocardiography detectec 18 vegetations in 17 of the 35 episodes of endocarditis studied (49 percen positive); two dimensional echocardiography detected 30 vegetations in 28 of the 35 episodes studied (80 percent positive). In contrast, nc vegetations were detected with technetium-99m stannous pyrophosphate scanning, and only two gallium-67 citrate scans were positive. The ad vantage of the two dimensional echocardiographic technique over al others tested was particularly notable for the identification of aortic and tricuspid valve vegetations.

The clinical diagnosis of endocarditis may now be confirmed by noninvasive methods that visualize endocardial vegetations. Several new techniques are currently being used for this purpose with varying results. M mode echocardiography has been employed in the detection of valve vegetations since the first reports of its usefulness in 1973.[1,2] The published sensitivity of this method ranged from 34 to 55 percent in series that included both right- and left-sided endocarditis.[3,4] Two dimensional echocardiography may be a more useful means of identifying vegetations since it provides a cross-sectional view of the cardiac structures, thus allowing more of the valve surfaces to be visualized. There are, however, conflicting reported data regarding the relative sensitivities of the M mode and two dimensional echocardiogram in detecting valve vegetations. Several reports[5,6] have shown the two dimensional to be superior to the M mode technique, whereas others[7,8] have indicated no difference between the two in their ability to detect vegetations.

Two recent studies of patients and animals with endocarditis have suggested that radionuclide imaging may prove to be an additional means of identifying valve vegetations. In one series, 7 of 11 patients with clinical endocarditis had a positive gallium-67 citrate cardiac scan, although the specific heart valve was not identifiable.[9] Technetium-99m stannous pyrophosphate scanning has shown abnormal accumulation of the isotope in experimentally induced Streptococcus sanguis endocarditis of the rabbit aortic valve.[10]

In this study, we attempted to determine the comparative usefulness of M mode echocardiography, two dimensional echocardiography, gallium-67 citrate scanning and technetium-99m stannous pyrophosphate imaging in the detection of valve vegetations in patients with infective endocarditis.

Methods

Patient Selection

From July 1978 through June 1979 78 consecutive patients admitted to Beth Israel Medical Center underwent evaluation for suspected infective endocarditis. A clinical diagnosis of infective endocarditis was based on the following strict criteria: temperature higher than 38° C; sustained bacteremia with at least three positive blood cultures; no other documented source of infection; and known underlying valve disease, a new or changing heart murmur or a history of intravenous drug abuse with radiologic evidence of septic pulmonary embolic phenomena.

Clinical features: Thirty-three patients with 35 episodes of endocarditis met these criteria for entry into the study. In 21 cases, right-sided endocarditis was diagnosed clinically on the basis of intravenous drug abuse and pulmonary emboli or a murmur consistent with tricuspid insufficiency (a blowing systolic murmur along the left sternal border that increased with inspiration). No attempt was made to distinguish between tricuspid and pulmonary valve endocarditis because the distinction was frequently not possible on the basis of clinical findings alone. Seven patients with holosystolic or late systolic apical murmurs that radiated to the axilla were believed to have mitral valve endocarditis. Aortic valve endocarditis was thought to be present clinically in five patients: Three patients had an aortic diastolic murmur and two had a murmur consistent with aortic stenosis. One patient with a history of intravenous drug abuse, multiple pulmonary emboli and a new aortic diastolic murmur was thought to have right-sided as well as aortic valve endocarditis. In an additional patient with a soft ejection systolic murmur along the left sternal border and paroxysmal atrial fibrillation, it was not clear which valve was involved.

Clinical data on these patients are summarized in Table 1. The patients ranged in age from 20 to 89 years (mean of 39). Six patients were women and 27 were men. Twenty-four patients had a history of intravenous drug abuse. Eight patients had a known history of cardiac valve disease before their first episode of endocarditis. No patient had clinical findings suggestive of systemic emboli; 21 had clinical findings consistent with septic pulmonary emboli. Two patients had two episodes of endocarditis during the study period. Patient 22 was successfully treated for Staphylococcus aureus endocarditis, but was subsequently discovered to have endocarditis with peptostreptococcus sp. 3 months later. Patient 33 returned with recurrent viridans streptococcal endocarditis 6 months after completion of his first course of therapy.

The infecting organisms included Staphylococcus aureus (22 patients), streptococcus viridans group (6 patients), Streptococcus bovis (4 patients), enterococcus (1 patient), Streptococcus pyogenes, Group A (1 patient) and peptostreptococcus sp. (1 patient). Correlation between the infecting organism and subsequent echocardiographic findings was attempted.

Forty-five patients did not meet strict criteria for infective endocarditis. This group included 19 women and 26 men ranging in age from 17 to 90 years (mean 48). Eleven patients had a known history of cardiac valve disease; 15 had a known history of intravenous drug abuse.

Echocardiography

M mode: All 78 patients underwent M mode followed by two dimensional echocardiographic studies during the 1st week of hospitalization. M mode echocardiographic examinations were carried out with a Unirad series 100 ultrasonascope interfaced with a Honeywell 1856-A strip chart recorder. Recordings were made in the usual manner utilizing previously described techniques.[11] Diagnostic criteria for the presence of valve vegetations included the presence of a localized mass of dense shaggy echoes creating an irregular thickening of the valve. Echoes that were linear rather than shaggy or irregular were interpreted as not being indicative of a vegetation.

Two dimensional echocardiography: This procedure was carried out with a commercially available real time phased array wide angle (80°) sector scanner (Varian Associates). Images were permanently recorded on videotape and Polaroid® photographs were made of stop action frame images. Studies were performed with the patients supine or in the left lateral decubitus position. The cardiac valves were examined by placing the transducer in three different positions (parasternal, apical, subxiphoid) and utilizing various transducer angulations. From each position, one or more tomographic sections of the heart were obtained by rotating the transducer. The transducer was initially placed in the third or fourth intercostal space to the left of the sternum to obtain a long axis and short axis view of the heart.[12] The apical four chambered view was then obtained by positioning the transducer at the point of maximal impulse and directing the ultrasonic beam toward the base of the heart in a plane parallel to the long axis of the left ventricle and perpendicular to the interventricular septum.[13] The subxiphoid view was recorded next by placing the transducer just below the xiphoid process, slightly to the right of the midline and directing the transducer superiorly toward the left supraclavicular fossa.[14] The diagnosis of a vegetation required the presence of a mobile, rapidly oscillating mass that was attached to or appeared to replace normal valve tissue. Increased valve thickness by itself was considered insufficient for the diagnosis of a vegetation.

All M mode and two dimensional echocardiograms were analyzed independently by at least two observers. In each case there was agreement about the presence or absence of vegetations.

Radionuclide Cardiac Imaging

Technetium-99m stannous pyrophosphate scan: Only those patients satisfying the clinical criteria for infective endocarditis were referred for radionuclide cardiac imaging. Thirty-one patients had technetium-99m stannous pyrophosphate studies performed; three patients refused to participate in this part of the protocol and one patient died before scanning could be done. The patients were given an intravenous injection of 15 mCi of technetium-99m stannous pyrophosphate and underwent scanning 3 to 4 hours later for evidence of focal cardiac accumulation. Images of 500,000 counts were obtained on a standard field camera with a convergent collimator in the anterior and 30° and 45° left anterior oblique projections.

Gallium-67 citrate scan: Immediately after the last pyrophosphate image was obtained, 6 to 7 mCi of gallium-67 citrate was injected intravenously in 30 patients. Initial scans were carried out at 24 hours with one to three follow-up examinations over the next 8 days after gallium injection. Twenty-eight patients returned for complete studies. Cardiac imaging was performed in the anterior and 30° and 45° left anterior oblique projections on a standard field gamma camera equipped with a high energy collimator with the camera set at 93 keV. Three hundred thousand counts were recorded per image; on some of the delayed images only 200,000 counts were obtained because of the prolonged scanning time required. In order to minimize imaging time and to ensure better patient cooperation, the most abundant gallium-67 photopeak was

* Does not include two additional aortic valve vegetations detected with two dimensional echocardiography but unsuspected clinically in two patients (Cases 1 and 11) with concomitant right-sided endocarditis.

AV = aortic valve; PV = pulmonary valve; TV = tricuspid valve.

ised with the recognition that a necessary loss of resolution night result.

All radionuclide scans were reviewed independently by at least two observers. In each case there was agreement regarding the interpretations.

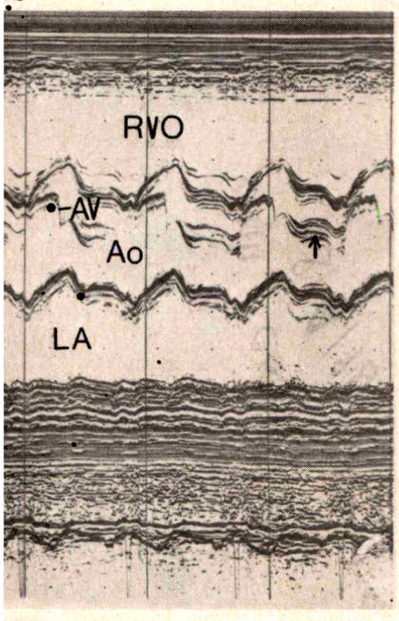
Surgical or autopsy confirmation was available in two patients. One patient died before operation; one patient had successful aortic valve replacement. An attempt was made to correlate the anatomic and echocardiographic findings in these two patients.

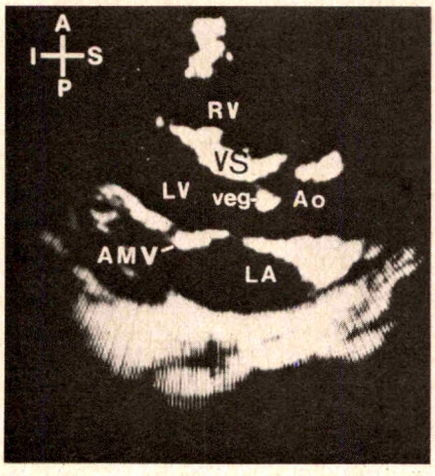
Statistical analysis was performed with the chi-square method.

Results

Echocardiograms: Among the 45 patients who did not meet the clinical criteria for endocarditis, no findings consistent with vegetative lesions were seen on either M mode or two dimensional echocardiography.

Echocardiographic findings in those patients meeting the clinical criteria for endocarditis are summarized in Table I. This group consisted of 33 patients with 35 episodes of endocarditis. Vegetations were visualized with two dimensional echocardiography in





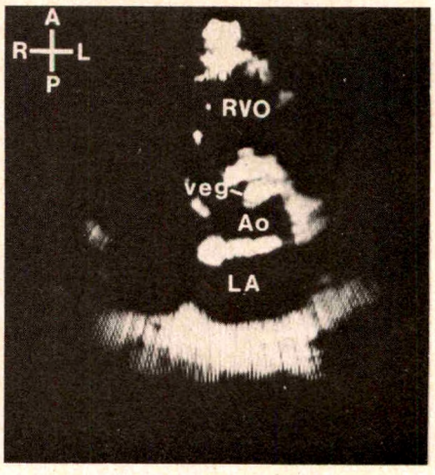


FIGURE 1 (left). Case 1. M mode echocardiogram of the aortic root (Ao). The **arrow** points to multiple linear diastolic echoes in the region of the aortic valve (AV). No definite vegetations are seen. LA = left atrium; RVO = right ventricular outflow tract.

FIGURE 2 (center and right). Same patient. Two dimensional echocardiogram showing long axis view of left heart **(center)** and short axis view at the level of the aortic root and left atrium **(right panel)**. A vegetation (veg) can be seen in the aortic root involving the left coronary cusp of the aortic valve. A = anterior; AMV = anterior leaflet of mitral valve; I = inferior; L = left; LV = left ventricle; P = posterior; R = right; RV = right ventricle; S = superior; other abbreviations as in Figure 1.

28 (80 percent) of the 35 episodes of endocarditis and with the M mode method in 17 episodes (49 percent) (Table II). A total of 30 valve vegetations were visualized in 28 patients with two dimensional echocardiography. Two patients had vegetations on both the aortic and the tricuspid valve: In one (Case 22A) involvement of both valves was suspected clinically; in the other (Case 11) only the tricuspid lesion was suspected. Patient 1 was thought clinically to have right-sided endocarditis; however, the two-dimensional echocardiogram revealed only an aortic valve vegetation and normal right-sided valves. By M mode technique, 18 valve vegetations were seen in 17 patients.

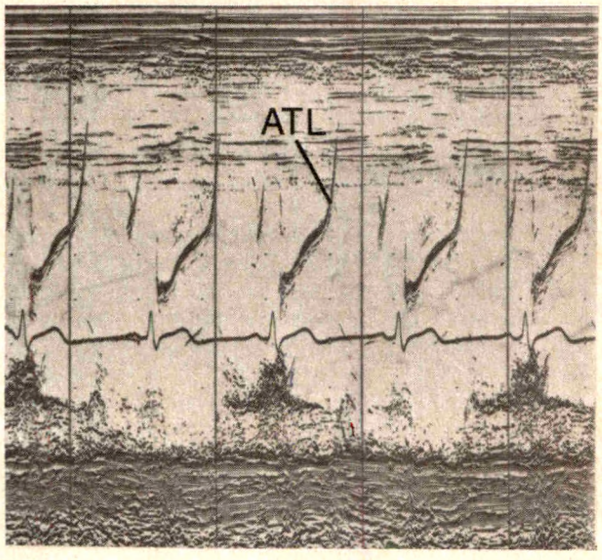
The valve distribution of vegetations suspected clinically and detected by echocardiography is summarized in Table III. The increased sensitivity of the two dimensional method was particularly evident in aortic and tricuspid vegetations. Figure 1 is an M mode echocardiogram from a patient with aortic valve endocarditis. There are a few increased linear diastolic echoes in the region of the aortic valve, but no definite vegetations are seen. Figure 2 is a two dimensional echocardiogram from this patient showing a vegetation on the left coronary cusp of the aortic valve. In Figure 3 a normal-appearing tricuspid valve is seen in the M mode echocardiogram. The two dimensional echocardiogram from this patient in Figure 4 shows a small polypoid vegetation on the anterior leaflet of the tricuspid valve.

Seven patients had no vegetations detectable with either echocardiographic method. No vegetations were detected with the M mode technique that were not demonstrated on two dimensional echocardiographic studies.

When the patients are categorized by infecting organisms, 20 of the 22 patients with Staphylococcus aureus had a positive two dimensional echocardiogram 12 of which were also positive on M mode examination. In contrast, only 8 of the 13 patients with nonstaphylococcal endocarditis had a positive two dimensional study and only 5 a positive M mode study.

Radionuclide scanning: All 31 patients studied with technetium-99m stannous pyrophosphate cardiac scanning had a negative scan. Of the 28 patients who had complete gallium-67 citrate isotope studies, two had a positive study. In the first patient (Case 23) a faint area of activity appeared between the sternum and the anterior costal margin at 24 hours and persisted at 4 and 6 days after injection of gallium. The second patient (Case 14) also had increased uptake at 24 hours in this area, which became brighter with repeated imaging on days 3 and 5 after injection of gallium. Both of these patients had two dimensional echocardiographic studies that showed valve vegetations. The results of the echocardiographic and radionuclide studies are compared in Table II.

Surgical or autopsy confirmation: Patient 27 had negative echocardiographic studies. Postmortem examination disclosed vegetations measuring 1 to 3 mm on all aortic cusps with aneurysmal dilatation and perforation of the mitral valve. Patient 22 underwent aortic valve replacement. This patient initially had Staphylococcus aureus endocarditis with vegetations on both the tricuspid and the aortic valve that had resolved on echocardiography at the completion of antibiotic therapy. The patient had clinical evidence of mild aortic insufficiency. Two months later when a second episode of endocarditis was discovered, new tricuspi



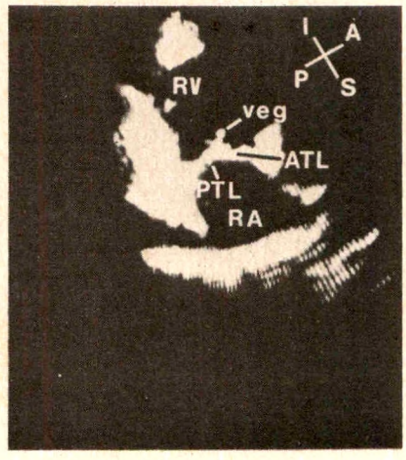


FIGURE 3 (left). Case 15. M mode echocardiogram showing normal anterior tricuspid leaflet (ATL).

A small vegetation (veg) is present on the ventricular side of the anterior tricuspid leaflet. PTL = posterior tricuspid leaflet; other abbreviations as before.

'egetations were seen on echocardiography; these again 'esolved during antibiotic therapy. At the time of aortic 'alve replacement the surgeon reported the tricuspid 'alve to be free of vegetations. Small vegetations were ıoted on pathologic examination of the aortic valve.

Discussion

Because the natural history and prognosis of endo-:arditis is in large part determined by the valve of ori-;in—with left-sided and particularly aortic valve dis-:ase associated with the most serious hemodynamic equelae—accurate identification of the infected heart 'alve becomes a vital component in patient manage-nent. This determination may not always be made with :ertainty on clinical grounds, especially when more than)ne valve is involved by the infectious process. Thus, a ıumber of recently developed noninvasive techniques ıave been applied for the detection of valve vegetations vith various degrees of success.

Advantages and applications of two dimensional :chocardiography: In the present study, valve vege-ations were identified by two dimensional echocardi-)graphy in 28 of 35 cases of endocarditis diagnosed linically. Whereas two dimensional echocardiography ncreased the number of vegetations detected with the tandard M mode technique in cases of aortic, mitral nd tricuspid endocarditis, its most distinct advantage 'as noted in visualization of aortic and tricuspid valve 'egetations. The finding of unsuspected aortic vegeta-ions in two patients with right-sided lesions and in one)atient in whom the involved valve could not be deter-ıined clinically proved to be a useful diagnostic aid. 'he observed increase in sensitivity with the two di-ıensional echocardiogram is related to better appre-iation of the spatial anatomy of the vegetations in elation to adjacent cardiac structures. In addition, the bility to examine the heart and its chambers from ıultiple transducer positions allows more complete isualization of valve leaflets and vegetative lesions.

The factors that account for echocardiographic vi-ualization of valve vegetations are complex. It has een established that vegetations must be greater than to 3 mm in size for M mode echocardiographic visu-lization.[15,16] In accord with these data, one of our pa-ients who had aortic valve vegetations measuring 1 to mm on postmortem examination had no vegetations etected with either two dimensional or M mode chocardiography. It has been observed in necropsy tudies[17] that tricuspid vegetations are generally larger ıan vegetations on other valves. In a series of 25 drug ddicts with endocarditis, the largest vegetations on chocardiographic evaluation were located on the tri-uspid valve.[18] The investigators postulated that the ırger anular circumference of the tricuspid valve, re-uced systolic pressure in the right ventricle and less 'equent incidence of ruptured tricuspid chordae al-)wed tricuspid vegetations to reach a larger size than ıitral valve vegetations.

There has also been some suggestion that vegetations ı patients infected with Staphylococcus aureus are ırger than vegetations in patients infected with other organisms. In a series of 65 echocardiographically evaluated patients with endocarditis, Staphylococcus aureus was noted to be more prevalent overall in the group of patients with vegetations on echocardiography, although only three of the patients in this series had tricuspid vegetations.[3] However, the investigators did not provide details of the anatomic findings. In our series it was difficult to assess the contribution of these various factors because 15 of the 18 patients with tricuspid valve vegetations on echocardiography had endocarditis due to Staphylococcus aureus.

Limitations of two dimensional echocardiography: In spite of the increased sensitivity of two dimensional echocardiography in demonstrating valve vegetations, the technique has several technical limitations. Improper use of gain settings may lead to erroneous estimation of the size of a vegetation, particularly when a phased array instrument is used. Gain settings set too high will make a vegetation appear larger than its actual size, whereas if the gain settings are set too low, image dropout may occur and the vegetation may appear smaller than it is or may be missed entirely. Furthermore, calcified or fibrotic valves and myxomatous degeneration may mimic vegetative lesions. Careful attention to technique will minimize these potential sources of error. However, there are some patients in whom a good quality echocardiogram cannot be obtained because of poor penetration of the ultrasonic beam due to interposed lung tissue or anatomic variation of the chest wall.

Technetium-99m pyrophosphate imaging in endocarditis: Cardiac scans with technetium-99m stannous pyrophosphate were negative in 31 of our patients with endocarditis who were so studied. These results were unexpected because technetium-99m stannous pyrophosphate scans in rabbits with infective and nonbacterial thrombotic endocarditis show focal uptake in the area surrounding the aortic valve vegetations and in the aortic outflow tract.[10] This radiopharmaceutical has been used successfully in both patients and animals to identify areas of acute myocardial infarction. The mechanism of its accumulation in recently necrotic myocardial tissue is still under investigation. It is known that both technetium-99m stannous pyrophosphate and calcium localize in mitochondria of acutely necrotic myocardium in animals with both acute myocardial infarction and necrosis secondary to endocarditis.[19] There is some recent evidence that technetium-99m stannous pyrophosphate also complexes with denatured protein macromolecules in these infarcted cells.[20]

There are several possible differences between patients with endocarditis and the animal model for this disease, which may explain the marked discrepancies between technetium-99m stannous pyrophosphate uptake in the animal study and in our series of patients with endocarditis. In the animal model there is probably more extensive necrosis of perivalvular and subendocardial tissue than occurs in patients with endocarditis. This would account for part of the perivalvular uptake on scanning in animals with endocarditis. The more acute the necrotic process, the more likely techne-

tium-99m stannous pyrophosphate is to accumulate in the damaged cell, as is seen in patients with myocardial infarction. Although our series included patients with both acute and subacute endocarditis, the duration of insult to adjacent myocardial cells is difficult to ascertain. Furthermore, the lesions in human endocarditis may be too small when compared with the animal model, and technically beyond the resolution of the collimator. Lastly, the experimentally induced vegetation may in fact not be comparable to the lesion of human acute endocarditis. In the animal study, uptake was similar in nonbacterial thrombotic endocarditis and infected lesions. While an initial valve platelet-fibrin thrombus is essential for the development of endocarditis in the animal model, there has been no histologic documentation that such lesions precede acute endocarditis in human beings.

Gallium-67 citrate imaging in endocarditis: In the present series, of 28 gallium-67 citrate scans performed, only 2 showed cardiac uptake, and neither positive study identified the involved heart valve. One patient had a subacute course with enterococcal endocarditis, and the other patient had acute endocarditis with Staphylococcus aureus. Their clinical courses did not differ from those of the remaining patients with a negative scan. In both patients valve vegetations were detected only with two dimensional echocardiography.

These findings are in contrast to six diffusely positive cardiac gallium scans in another series of 11 patients with endocarditis.[9] All but one of the patients had left-sided endocarditis and four of the six patients with a positive scan were infected with Staphylococcus aureus. These scans became positive between 3 and 8 days after isotope injection, whereas in our two patients with a positive gallium study the scan showed abnormal uptake at 24 hours and remained positive.

Some gallium uptake might be expected in all patients with endocarditis, because necropsy studies show myocardial inflammation in up to 60 percent or more of patients with endocarditis.[21] This is most prominent in left-sided and possibly in subacute disease.[17,22,23] Gallium presumably localizes in infected tissue by binding to polymorphonuclear leukocytes, which then accumulate in areas of acute infection. In addition, accumulation of gallium may occur as a result of increased vascularity in infected sites, tissue deposition of gallium-transferrin complexes and binding of gallium to microorganisms.[24]

There are several possible explanations to account for the discrepancies between our series and the previously cited gallium scanning study.[9] Right-sided endocarditis predominated in our series of patients. The anulus and surrounding myocardium are known to have markedly less involvement in tricuspid endocarditis than in left sided diseases.[17] Less gallium uptake might be anticipated on this basis. In addition, early antibiotic therapy has been shown to decrease leukocyte migration to infected tissue.[25] In all of our patients treatment had been initiated before gallium scanning was carried out. Furthermore, the majority of our patients probably had a more acute inflammatory process than those in the previously cited study in which five of the six patients underwent imaging at least 18 days after the onset of their symptoms. Lastly, because of the uncooperative attitude of many of our patients, an attempt was made to shorten the study time by using the more abundant lower photopeak of gallium. The resolution loss may have made subtle abnormalities undetectable. In the study by Wiseman et al.[9], 100,000–200,000 counts required 30 minutes imaging time, which we considered to be beyond the tolerance of the majority of our patients.

In our series of patients with endocarditis, technetium-99m stannous pyrophosphate and gallium scans had extremely low sensitivity in identifying valvular vegetations. A recent case report of focal accumulation of gallium-67 citrate in the left ventricle of a patient with surgically confirmed myocardial abscess suggests that scanning might find application in the demonstration of suppurative complications of endocarditis.[26] Echocardiography, and most notably the two dimensional technique, remains the only sensitive method for detecting valve vegetations in patients with endocarditis.

Acknowledgment

We are grateful to Mannil Abraham for valuable technical assistance, to Fernando Costales, MD, for advice in the statistical analysis, to Fukiat Ongseng, MD for assistance in performing the radionuclide studies, and to Mansoor Jelveh, MD for reviewing the M mode and two dimensional echocardiographic studies.

Pulsed Doppler Echocardiographic Detection of Right-Sided Valve Regurgitation

Experimental Results and Clinical Significance

Pulsed Doppler echocardiography may allow noninvasive detection of tricuspid insufficiency as disturbed or turbulent systolic flow in the right atrium and pulmonary insufficiency as turbulent diastolic flow in the right ventricular outflow tract. Accordingly, six open chest mongrel dogs were examined with Doppler echocardiography before and after surgical creation of tricuspid and pulmonary insufficiency. The Doppler technique detected the appropriate lesion in all instances, with a specificity of 100 percent.

In 121 patients (20 without heart disease, 101 with heart disease of various causes), pulsed Doppler echocardiography was used to detect right-sided valve regurgitation. Results were compared with right-sided pressure measurements and M mode echocardiographic findings in all, and with right ventricular angiography in 21 patients. Pulsed Doppler study detected tricuspid insufficiency in 61 of 100 patients, 12 (20 percent) of whom had clinical evidence of this lesion. Angiographic evidence of tricuspid regurgitation was present in 18 patients, 17 of whom had positive Doppler findings (sensitivity 94 percent), and absent in 3, all with negative Doppler findings. Pulmonary insufficiency was found on pulsed Doppler study in 47 of 91 patients, 3 of whom (all after pulmonary valvotomy) had clinical evidence of this lesion. Increased right ventricular systolic pressure (greater than 35 mm Hg) was noted more often in patients with (55 of 61 or 90 percent) than in those without (22 of 59 or 37 percent) tricuspid insufficiency ($p < 0.01$). Pulmonary arterial mean pressure was elevated (22 mm Hg or less) more often in patients with (38 of 43 or 88 percent) than in those without (24 of 64 or 38 percent) pulmonary insufficiency ($p < 0.01$).

Thus, pulsed Doppler echocardiography appears to be an accurate noninvasive technique for detection of right-sided valve regurgitation. The absence of diagnostic physical findings in many of the patients indicates that the hemodynamic severity of the Doppler-detected valve insufficiency was probably insignificant. However, because of its high incidence rate (87 percent) and association with pulmonary hypertension (87 percent), pulsed Doppler detection of tricuspid or pulmonary insufficiency, or both (in the absence of pulmonary stenosis) was found superior to M mode echocardiographic measurements (right ventricular size, pulmonary valve motion) in the prediction of pulmonary hypertension.

The clinical detection of right-sided valve regurgitation of either tricuspid or pulmonary origin may often be difficult.[1–3] Tricuspid insufficiency may occur as a functional result of right ventricular pressure or volume overload or may be caused by infective endocarditis, congenital malformations, trauma and, infrequently, carcinoid disease.[2,4] Pulmonary insufficiency, as an isolated lesion, has been shown to be well tolerated and seldom leads to right ventricular failure. When symptoms occur, pulmonary hypertension or additional disease must be suspected.[5–10] Thus detection of right-sided valve regurgitation may assume clinical importance as a marker of a more serious underlying disease process, particularly in patients with coexistent left-sided heart disease.

Invasive procedures such as angiography have certain mitations in the identification of right-sided valve sufficiency but are probably reliable to establish the)sence of valve regurgitation.[10–12] Intracardiac pho-)cardiography may be superior to angiography in the :tection of pulmonary insufficiency.[12] Although)ninvasive techniques such as M mode echocardiog-.phy and phonocardiography are relatively insensitive dicators of right-sided valve insufficiency, echocar-ography can provide useful information on right ntricular size, abnormalities of ventricular septal otion due to right ventricular volume overload and)normalities of pulmonary valve motion that may ggest the presence of pulmonary hypertension. An curate noninvasive technique to detect right-sided lve regurgitation could therefore be of considerable inical value when results of cardiac catheterization or)ninvasive tests are not entirely diagnostic.

Pulsed Doppler echocardiography is a new noninva-ve technique that allows qualitative assessment of ood flow patterns within intracardiac chambers and us may be useful in detecting the presence of valve sufficiency or stenosis as well as a variety of congenital art defects.[13–22] The presence of disturbed or turbu-nt flow in the right atrium during systole or in the right ntricular outflow tract during diastole has been pre-med to be indicative of tricuspid or pulmonary in-fficiency, respectively. In the present study we in-stigated the sensitivity and specificity of pulsed)ppler echocardiography in detecting experimentally duced right-sided valve regurgitation. In addition, we tempted to determine the clinical significance of these ndings in patients with evidence of organic heart dis-e of various causes.

Methods

chnical Description and Procedure

Pulsed Doppler echocardiograms were performed ilizing a commercially available Echo-Doppler unit dvanced Technology Laboratories, Seattle, Wash-gton) that uses repetitive pulses of sound in a mega-rtz range similar to that of traditional M mode hocardiography. Its primary advantage over contin-)us wave Doppler recording is that the Doppler shift oduced by the velocity of blood flow can be recorded localized intracardiac positions at several depths by eans of a range-gating system.

The principle of the Doppler effect has been re-)rted previously.[14] In brief, the frequency of a re-cted sound wave is altered when the reflecting target in motion. When an ultrasonic beam is directed at nturbulent or laminar blood flow, the reflected sound ves exhibit a fairly uniform shift in frequency or)oppler shift" in either a positive or negative direction pending on the direction of flow toward or away from e transducer; the magnitude of the shift is related to th the velocity of flow and the angle of incidence be-een flow and sound. In contrast, when the ultrasonic am is directed toward turbulent blood flow, the re-cted sound waves undergo a wide and random shift frequency due to the varying velocity and direction the blood cells in the turbulent area.

The instrument consists of a 3 megahertz piezoelectric transducer with a ½ inch (1.27 cm) diameter crystal focused at 5 cm that emits 1 ms ultrasonic bursts at a pulse repetition frequency of 3,500 to 10,000 bursts/s. The returned signal is divided so that a portion is processed to create a traditional M mode display for depth reference while the remainder is used to detect the Doppler shifts. A movable range-gating system electronically creates a 2 by 4 mm teardrop-shaped area for discrete sampling of Doppler shifts at any depth selected from 2 to 15 cm along the ultrasonic beam. The Doppler effect is displayed using both an audio system and a graphic system referred to as a time interval histogram. Interpretation of the audio signal is based on its tonal quality; nonturbulent blood flow has a narrow band width pattern producing a rather musical sound, whereas turbulent flow tends to have a wide band width pattern, producing a harsh, scratchy sound. The time interval histogram interprets frequency shifts of the reflected ultrasound utilizing a zero-crossing technique previously described.[15] The graphic display consists of a series of dots printed above (positive shift) or below (negative shift) a baseline, the distance away from baseline reflecting the magnitude of the shift. The conventional display contains the M mode echocardiogram with a superimposed line indicating location of the sample volume, an electrocardiogram and the time interval histogram (Fig. 1).

Clinical Studies

Tricuspid insufficiency: *The technique employed in the clinical studies was as follows (Fig. 1):* The 3.0 megahertz transducer was placed along the left sternal border in a manner similar to that used for standard M mode echocardiography and directed medially to record the tricuspid valve. The sample volume was then placed in the right atrium slightly posterior to the systolic motion of the tricuspid valve echo and anterior to the atrial septum. After the instrument gain was set to an optimal signal to noise ratio, systolic turbulence was sought by moving the sample volume within the space posterior to the tricuspid valve (right atrium) while carefully listening for turbulent sounds from the speakers. However, regardless of the audio signals, the diagnosis of tricuspid insufficiency depended on the objective interpretation of the time interval histogram for the presence of systolic turbulence in the right atrium. Threshold levels in the instrument were set to the maximal possible level that allowed adequate signal recording with minimal baseline noise. On the basis of our previous experience with left-side valve regurgitation[22] and with aortic stenosis,[16] we defined turbulence on the time interval histogram as a frequency dispersion greater than 1 cm in amplitude. The amplitude and duration of turbulence were measured (Fig. 1). The duration of turbulence was expressed as a fraction of the duration of systole.

Pulmonary insufficiency (Fig. 2): The presence or absence of pulmonary insufficiency was assessed by directing the transducer superiorly and leftward from the aortic root to record the pulmonary valve. The sample volume was then placed in the echo-free space

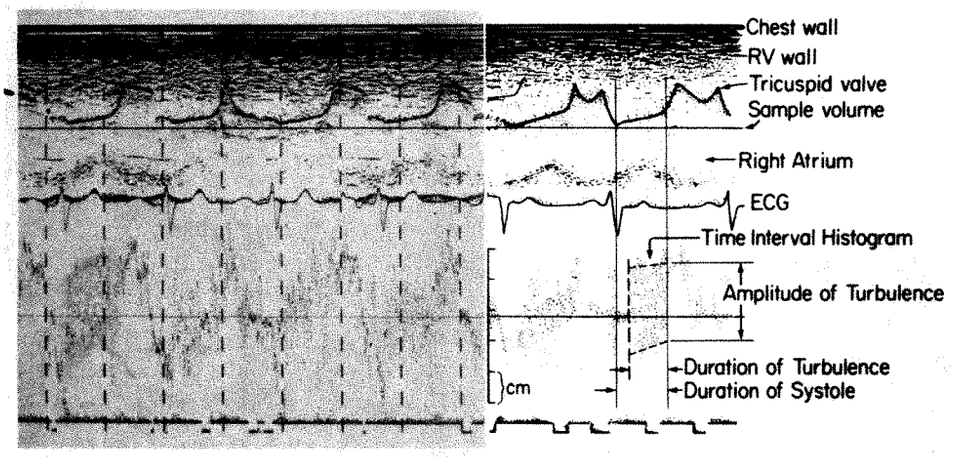

FIGURE 1. Pulsed Doppler echocar diographic examination in a patient wit tricuspid insufficiency. **Top half,** mode echocardiogram indicating lo cation of the sample volume posteric to the tricuspid valve in the right atrium **Bottom half,** time interval histogram Note the wide dispersion of **dots** abov and below a zero frequency shi baseline during systole, indicatin systolic turbulence in the right atrium The amplitude and duration of turbu lence and the duration of systole ar outlined by **interrupted lines** in the d agram on the **right.** The positive un form frequency shifts during diastol are produced by the normal diastoli inflow across the tricuspid valve. anterior to the pulmonary valve echo representing the right ventricular outflow tract. Care was taken not to place the sample volume through the pulmonary valve orifice or distal to the valve in the pulmonary artery. Whenever the pulmonary valve echo could not be well visualized, the transducer was directed toward the pulmonary valve area, gradually moving the sample volume until the characteristic opening and closing clicks of the valve were heard. The sample volume was then moved anteriorly into the right ventricular outflow tract. Diastolic turbulence was sought while the sample volume was moved within the right ventricular outflow and by carefully listening for turbulent sound from the speakers. However, the diagnosis of pulmonary insufficiency depended on the objective interpretation of the time interval histogram for the presence of a wide (greater than 1 cm) frequency dispersion. The amplitude in absolute centimeters and the duration of the diastolic turbulence (expressed as a fraction of diastole) were measured as shown in Figure 2.

All patients underwent a complete pulsed Doppler examination including the left side of the heart for the presence of mitral or aortic regurgitation as well as aortic stenosis utilizing standard techniques previously reported from this laboratory.[16,22] Interpretation of the time interval histogram for evidence of tricuspid or pulmonary insufficiency was performed by two separat observers without knowledge of the clinical, angio graphic or hemodynamic data available on each pa tient.

Study patients: A total of 121 patients were studie with both M mode and pulsed Doppler echocardiogra phy. Twenty patients (12 men and 8 women with a mea age 41 years [range 25 to 62]) without clinical, electro cardiographic or M mode echocardiographic evidenc of organic heart disease served as normal contro subjects. One hundred one patients (50 male and 5 female with a mean age 44 years [range 2 to 83]) wit evidence of heart disease of various causes (Table I were selected in a consecutive manner on the basis o two criteria: (1) the indications for diagnostic right and left heart catheterization, and (2) the diagnostic quality of a standard M mode echocardiogram. Valvular hear disease was present in 60 percent of the patients an congenital heart disease was the second most commo abnormality (25 percent). Pulsed Doppler studies wer technically inadequate for detection of tricuspid o pulmonary insufficiency in 1 and 10 patients, respec tively.

All 101 patients underwent diagnostic right and lef heart catheterization utilizing standard techniques Right ventricular angiography was performed in the 20

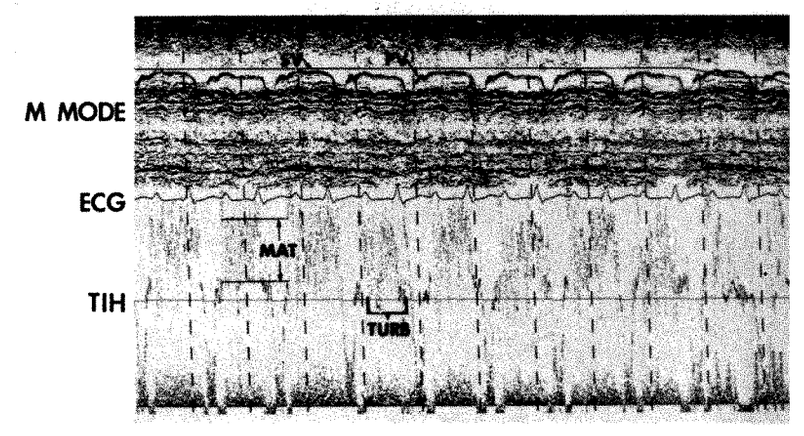

FIGURE 2. Pulsed Doppler echocardiographic examination in a patient with pulmonary insufficiency. The sample volume (SV) is located anterior to the pulmonary valve (PV) in the right ventricular outflow tract. Note the negative smooth flow-velocity curve in the time interval histogram (TIH) during systole produced by the blood flowing away from the sound waves, and the wide frequency dispersion (indicating turbulence) that extends through most of diastole. In the **far right** portion of the figure (the last two cardiac cycles), the sample volume is repositioned within the pulmonary valve and diastolic turbulence (TURB) is no longer demonstrated in the time interval histogram. ECG = electrocardiogram; MAT = maximal amplitude turbulence.

* All patients had mitral valve disease. †Includes three patients with pulmonary valvotomy.
AF = atrial fibrillation (idiopathic); APVR = anomalous pulmonary venous return; ASD = atrial septal defect; AVD = aortic valve disease; CAD = coronary artery disease; MVD = mitral valve disease; PH = pulmonary hypertension; PI = pulmonary insufficiency; PS = pulmonary stenosis; TA = tricuspid atresia; TI = tricuspid insufficiency; VSD = ventricular septal defect.

right anterior oblique projection in 21 patients with injection of 40 to 50 cc of Renografin® 76 through a side hole angiographic catheter at a rate of 10 cc/s. Ventricular ectopic beats were excluded from evaluation.

Experimental Studies

Six open chest mongrel dogs were examined with M mode and pulsed Doppler echocardiography by manually placing the transducer on the anterior surface of the heart and directing the sound waves into the tricuspid valve with the right atrium behind it or into the right ventricular outflow tract and pulmonary valve. Experimental right-sided valve regurgitation was accomplished by suturing one or more leaflets of the particular valve to the valve ring. In each animal, 10 cc of normal saline solution was injected rapidly through a flow-directed catheter inserted into the right ventricle or pulmonary artery through the left jugular vein in order to create microcavitations that could be recorded on the M mode echocardiogram. Thus we could establish the presence of valve regurgitation by the appearance of microcavitations in the right atrium during systole (indicating tricuspid insufficiency) or in the right ventricular outflow tract in diastole (indicating pulmonary insufficiency). The pulsed Doppler examinations were performed in a manner analogous to the clinical studies. At the completion of the study, the animals were killed and the hearts examined to ensure proper placement of the sutures and disruption of valve competency.

Statistical analysis: Statistical evaluation was carried out by chi-square analysis; significance was established at a level of $p < 0.05$.

Results

Experimental Studies

None of the six dogs had evidence of tricuspid or pulmonary insufficiency by microcavitations or by pulsed Doppler echocardiography before surgical valve disruption or with placement of the catheter through the valve orifices. Microcavitations were observed in the right atrium during systole or in the right ventricular outflow tract during diastole in each animal with surgical induction of tricuspid or pulmonary insufficiency, respectively (Fig. 3 A and C). In each instance, the pulsed Doppler recording was also diagnostic of tricuspid or pulmonary insufficiency (Fig. 3 B and D). Thus the sensitivity of pulsed Doppler echocardiography in detecting experimental tricuspid pulmonary insufficiency was 100 percent. The specificity of the technique was also 100 percent.

Clinical Studies

None of the 20 patients without clinical evidence of heart disease had Doppler evidence of systolic turbulent flow in the right atrium or diastolic turbulent flow in the right ventricular outflow tract. Table I lists the diagnoses and the incidence of flow disturbances in the 101 patients with heart disease. Flow disturbances compatible with tricuspid or pulmonary insufficiency, or both, were frequently found on Doppler recording in patients with rheumatic heart disease, congenital heart disease and cardiomyopathy. In total, Doppler evidence of tricuspid insufficiency was found in 61 of 100 patients and pulmonary insufficiency in 47 of 91 patients with adequate studies. Thirty-one patients had evidence of both lesions.

Tricuspid insufficiency: A systolic murmur compatible with tricuspid insufficiency was audible in 12 of 61 patients (20 percent) with Doppler evidence of tricuspid regurgitation and in none of the 39 patients without tricuspid insufficiency on Doppler recording. Comparison of Doppler findings with right ventriculography in 21 patients revealed angiographic evidence of tricuspid regurgitation in all 17 patients with a positive Doppler study and absence of this lesion in 3 of 4

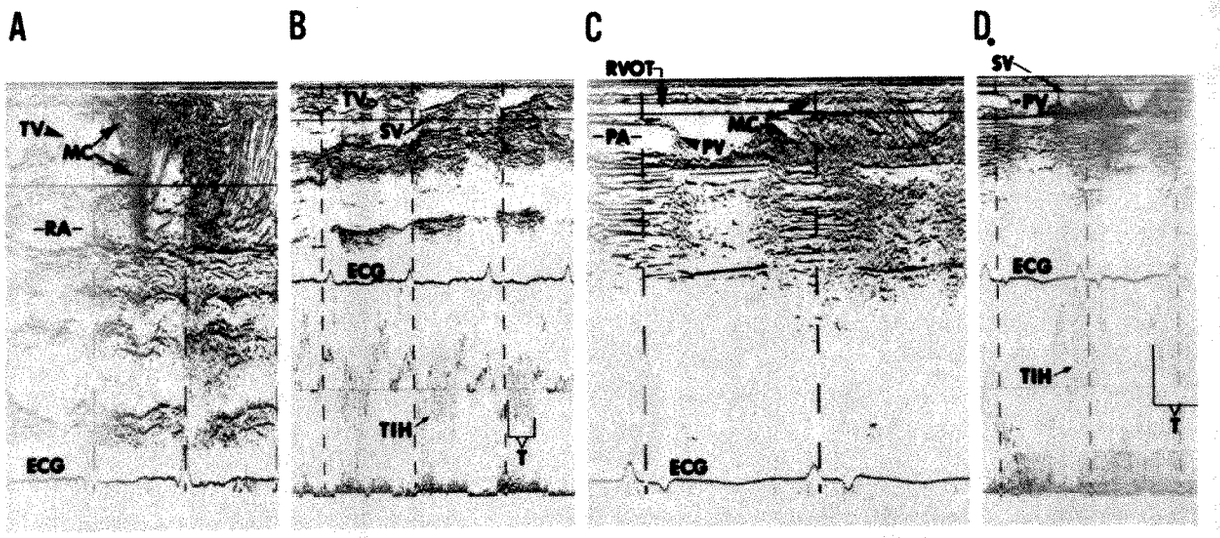

FIGURE 3. A, M mode echocardiogram of the regurgitant tricuspid valve (TV) in an open chest dog. After rapid injection of saline solution into th right ventricle, microcavitations (MC) appear initially in the right ventricular inflow tract and subsequently in the right atrium (RA), a finding consister with tricuspid insufficiency. **B,** pulsed Doppler echocardiogram from the same animal demonstrating systolic turbulence (T) in the time interv histogram (TIH) with the sample volume (SV) placed beneath the tricuspid valve in the right atrium. **C,** M mode echocardiogram of the regurgitar pulmonary valve (PV) demonstrating the injection of saline solution into the pulmonary artery (PA) and rapid visualization of microcavitations i the right ventricular outflow tract (RVOT) during diastole, a finding diagnostic of pulmonary insufficiency. **D,** pulsed Doppler echocardiogram fro the same animal demonstrating diastolic turbulence in the time interval histogram with the sample volume located in the right ventricular outflo tract. ECG = electrocardiogram.

patients with a negative Doppler study; the sensitivity of pulsed Doppler echocardiography against angiography was therefore 94 percent.

The relation of Doppler evidence of tricuspid regurgitation to the presence of right ventricular pressure overload is shown in Table II. Chi-square analysis revealed a significant ($p < 0.01$) association between the two abnormalities; 90 percent of patients with versus 37 percent of those without tricuspid insufficiency on Doppler study had a systolic right ventricular pressure greater than 35 mm Hg. Furthermore, the incidence of systolic turbulence in the right atrium compatible with tricuspid insufficiency in patients with and without increased right ventricular pressure was 71 and 14 percent, respectively.

Pulmonary insufficiency: A basal diastolic low pitched murmur was audible in the three patients with previous pulmonary valvotomy; all three also had evidence on Doppler recording of disturbed or turbulent diastolic flow in the right ventricular outflow tract. A basal diastolic high pitched murmur was audible in 35 patients, 20 with and 15 without diastolic turbulence in the right ventricular outflow; all 35 patients had evidence of aortic insufficiency on Doppler study (35 patients) or angiography (33 patients).

A significant association was observed between Doppler evidence of pulmonary insufficiency and pulmonary hypertension (Table III); 86 percent of the patients (excluding the three patients with previous valvotomy) with versus 38 percent of those without diastolic turbulence in the right ventricular outflow tract had a mean pulmonary arterial pressure greater than 22 mm Hg ($p < 0.01$). Furthermore, the incidence of diastolic turbulence in the right ventricular outflow tract in patients with and without pulmonary hypertension was 61 and 13 percent, respectively. Doppler evidence of pulmonary insufficiency with normal pulmonary pressure was present in six patients: two with a left to right shunt at the atrial level, two with cardiomyopathy, one with mitral stenosis and one with pulmonary valve stenosis.
